    select c;

// anon is compiled as an anonymous type
var anon = new { Name = "Terry", Age = 34 };

// list is compiled as List<int>
var list = new List<int>();
```

It is important to understand that the `var` keyword does not mean "variant" and does not indicate that the variable is loosely typed, or late-bound. It just means that the compiler determines and assigns the most appropriate type.

The `var` keyword may be used in the following contexts:

- On local variables (variables declared at method scope) as shown in the previous example.
- In a `for` initialization statement.

```
for (var x = 1; x < 10; x++)
```

- In a `foreach` initialization statement.

```
foreach (var item in list) {...}
```

- In a `using` statement.

```
using (var file = new StreamReader("C:\\myfile.txt")) {...}
```

For more information, see [How to use implicitly typed local variables and arrays in a query expression](#).

var and anonymous types

In many cases the use of `var` is optional and is just a syntactic convenience. However, when a variable is initialized with an anonymous type you must declare the variable as `var` if you need to access the properties of the object at a later point. This is a common scenario in LINQ query expressions. For more information, see [Anonymous Types](#).

From the perspective of your source code, an anonymous type has no name. Therefore, if a query variable has been initialized with `var`, then the only way to access the properties in the returned sequence of objects is to use `var` as the type of the iteration variable in the `foreach` statement.

```
class ImplicitlyTypedLocals2
{
    static void Main()
    {
        string[] words = { "aPPLE", "BlUeBeRrY", "cHeRry" };

        // If a query produces a sequence of anonymous types,
        // then use var in the foreach statement to access the properties.
        var upperLowerWords =
            from w in words
            select new { Upper = w.ToUpper(), Lower = w.ToLower() };

        // Execute the query
        foreach (var ul in upperLowerWords)
        {
            Console.WriteLine("Uppercase: {0}, Lowercase: {1}", ul.Upper, ul.Lower);
        }
    }
}

/* Outputs:
    Uppercase: APPLE, Lowercase: apple
    Uppercase: BLUEBERRY, Lowercase: blueberry
    Uppercase: CHERRY, Lowercase: cherry
*/
```

Remarks

The following restrictions apply to implicitly-typed variable declarations:

- `var` can only be used when a local variable is declared and initialized in the same statement; the variable cannot be initialized to null, or to a method group or an anonymous function.
- `var` cannot be used on fields at class scope.
- Variables declared by using `var` cannot be used in the initialization expression. In other words, this expression is legal: `int i = (i = 20);` but this expression produces a compile-time error:
`var i = (i = 20);`
- Multiple implicitly-typed variables cannot be initialized in the same statement.
- If a type named `var` is in scope, then the `var` keyword will resolve to that type name and will not be treated as part of an implicitly typed local variable declaration.

Implicit typing with the `var` keyword can only be applied to variables at local method scope. Implicit typing is not available for class fields as the C# compiler would encounter a logical paradox as it processed the code: the compiler needs to know the type of the field, but it cannot determine the type until the assignment expression is

analyzed, and the expression cannot be evaluated without knowing the type. Consider the following code:

```
private var bookTitles;
```

`bookTitles` is a class field given the type `var`. As the field has no expression to evaluate, it is impossible for the compiler to infer what type `bookTitles` is supposed to be. In addition, adding an expression to the field (like you would for a local variable) is also insufficient:

```
private var bookTitles = new List<string>();
```

When the compiler encounters fields during code compilation, it records each field's type before processing any expressions associated with it. The compiler encounters the same paradox trying to parse `bookTitles`: it needs to know the type of the field, but the compiler would normally determine `var`'s type by analyzing the expression, which isn't possible without knowing the type beforehand.

You may find that `var` can also be useful with query expressions in which the exact constructed type of the query variable is difficult to determine. This can occur with grouping and ordering operations.

The `var` keyword can also be useful when the specific type of the variable is tedious to type on the keyboard, or is obvious, or does not add to the readability of the code. One example where `var` is helpful in this manner is with nested generic types such as those used with group operations. In the following query, the type of the query variable is `IEnumerable<IGrouping<string, Student>>`. As long as you and others who must maintain your code understand this, there is no problem with using implicit typing for convenience and brevity.

```
// Same as previous example except we use the entire last name as a key.  
// Query variable is an IEnumerable<IGrouping<string, Student>>  
var studentQuery3 =  
    from student in students  
    group student by student.Last;
```

The use of `var` helps simplify your code, but its use should be restricted to cases where it is required, or when it makes your code easier to read. For more information about when to use `var` properly, see the [Implicitly typed local variables](#) section on the C# Coding Guidelines article.

How to use implicitly typed local variables and arrays in a query expression (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

You can use implicitly typed local variables whenever you want the compiler to determine the type of a local variable. You must use implicitly typed local variables to store anonymous types, which are often used in query expressions. The following examples illustrate both optional and required uses of implicitly typed local variables in queries.

Implicitly typed local variables are declared by using the `var` contextual keyword. For more information, see [Implicitly Typed Local Variables](#) and [Implicitly Typed Arrays](#).

Examples

The following example shows a common scenario in which the `var` keyword is required: a query expression that produces a sequence of anonymous types. In this scenario, both the query variable and the iteration variable in the `foreach` statement must be implicitly typed by using `var` because you do not have access to a type name for the anonymous type. For more information about anonymous types, see [Anonymous Types](#).

```
private static void QueryNames(char firstLetter)
{
    // Create the query. Use of var is required because
    // the query produces a sequence of anonymous types:
    // System.Collections.Generic.IEnumerable<??>.
    var studentQuery =
        from student in students
        where student.FirstName[0] == firstLetter
        select new { student.FirstName, student.LastName };

    // Execute the query and display the results.
    foreach (var anonType in studentQuery)
    {
        Console.WriteLine("First = {0}, Last = {1}", anonType.FirstName, anonType.LastName);
    }
}
```

The following example uses the `var` keyword in a situation that is similar, but in which the use of `var` is optional. Because `student.LastName` is a string, execution of the query returns a sequence of strings. Therefore, the type of `queryID` could be declared as `System.Collections.Generic.IEnumerable<string>` instead of `var`. Keyword `var` is used for convenience. In the example, the iteration variable in the `foreach` statement is explicitly typed as a string, but it could instead be declared by using `var`. Because the type of the iteration variable is not an anonymous type, the use of `var` is an option, not a requirement. Remember, `var` itself is not a type, but an instruction to the compiler to infer and assign the type.

```
// Variable queryId could be declared by using
// System.Collections.Generic.IEnumerable<string>
// instead of var.
var queryId =
    from student in students
    where student.Id > 111
    select student.LastName;

// Variable str could be declared by using var instead of string.
foreach (string str in queryId)
{
    Console.WriteLine("Last name: {0}", str);
}
```

Extension Methods (C# Programming Guide)

12/28/2021 • 10 minutes to read • [Edit Online](#)

Extension methods enable you to "add" methods to existing types without creating a new derived type, recompiling, or otherwise modifying the original type. Extension methods are static methods, but they're called as if they were instance methods on the extended type. For client code written in C#, F# and Visual Basic, there's no apparent difference between calling an extension method and the methods defined in a type.

The most common extension methods are the LINQ standard query operators that add query functionality to the existing [System.Collections.IEnumerable](#) and [System.Collections.Generic.IEnumerable<T>](#) types. To use the standard query operators, first bring them into scope with a `using System.Linq` directive. Then any type that implements [IEnumerable<T>](#) appears to have instance methods such as [GroupBy](#), [OrderBy](#), [Average](#), and so on. You can see these additional methods in IntelliSense statement completion when you type "dot" after an instance of an [IEnumerable<T>](#) type such as [List<T>](#) or [Array](#).

OrderBy Example

The following example shows how to call the standard query operator `OrderBy` method on an array of integers. The expression in parentheses is a lambda expression. Many standard query operators take lambda expressions as parameters, but this isn't a requirement for extension methods. For more information, see [Lambda Expressions](#).

```
class ExtensionMethods2
{
    static void Main()
    {
        int[] ints = { 10, 45, 15, 39, 21, 26 };
        var result = ints.OrderBy(g => g);
        foreach (var i in result)
        {
            System.Console.Write(i + " ");
        }
    }
}
//Output: 10 15 21 26 39 45
```

Extension methods are defined as static methods but are called by using instance method syntax. Their first parameter specifies which type the method operates on. The parameter is preceded by the [this](#) modifier. Extension methods are only in scope when you explicitly import the namespace into your source code with a `using` directive.

The following example shows an extension method defined for the [System.String](#) class. It's defined inside a non-nested, non-generic static class:

```
namespace ExtensionMethods
{
    public static class MyExtensions
    {
        public static int WordCount(this String str)
        {
            return str.Split(new char[] { ' ', '.', '?' },
                            StringSplitOptions.RemoveEmptyEntries).Length;
        }
    }
}
```

The `WordCount` extension method can be brought into scope with this `using` directive:

```
using ExtensionMethods;
```

And it can be called from an application by using this syntax:

```
string s = "Hello Extension Methods";
int i = s.WordCount();
```

You invoke the extension method in your code with instance method syntax. The intermediate language (IL) generated by the compiler translates your code into a call on the static method. The principle of encapsulation is not really being violated. Extension methods cannot access private variables in the type they are extending.

Both the `MyExtensions` class and the `WordCount` method are `static`, and it can be accessed like all other `static` members. The `WordCount` method can be invoked like other `static` methods as follows:

```
string s = "Hello Extension Methods";
int i = MyExtensions.WordCount(s);
```

The preceding C# code:

- Declares and assigns a new `string` named `s` with a value of `"Hello Extension Methods"`.
- Calls `MyExtensions.WordCount` given argument `s`

For more information, see [How to implement and call a custom extension method](#).

In general, you'll probably be calling extension methods far more often than implementing your own. Because extension methods are called by using instance method syntax, no special knowledge is required to use them from client code. To enable extension methods for a particular type, just add a `using` directive for the namespace in which the methods are defined. For example, to use the standard query operators, add this `using` directive to your code:

```
using System.Linq;
```

(You may also have to add a reference to `System.Core.dll`.) You'll notice that the standard query operators now appear in IntelliSense as additional methods available for most `IEnumerable<T>` types.

Binding Extension Methods at Compile Time

You can use extension methods to extend a class or interface, but not to override them. An extension method with the same name and signature as an interface or class method will never be called. At compile time, extension methods always have lower priority than instance methods defined in the type itself. In other words, if

a type has a method named `Process(int i)`, and you have an extension method with the same signature, the compiler will always bind to the instance method. When the compiler encounters a method invocation, it first looks for a match in the type's instance methods. If no match is found, it will search for any extension methods that are defined for the type, and bind to the first extension method that it finds. The following example demonstrates how the compiler determines which extension method or instance method to bind to.

Example

The following example demonstrates the rules that the C# compiler follows in determining whether to bind a method call to an instance method on the type, or to an extension method. The static class `Extensions` contains extension methods defined for any type that implements `IMyInterface`. Classes `A`, `B`, and `C` all implement the interface.

The `MethodB` extension method is never called because its name and signature exactly match methods already implemented by the classes.

When the compiler can't find an instance method with a matching signature, it will bind to a matching extension method if one exists.

```
// Define an interface named IMyInterface.
namespace DefineIMyInterface
{
    using System;

    public interface IMyInterface
    {
        // Any class that implements IMyInterface must define a method
        // that matches the following signature.
        void MethodB();
    }
}

// Define extension methods for IMyInterface.
namespace Extensions
{
    using System;
    using DefineIMyInterface;

    // The following extension methods can be accessed by instances of any
    // class that implements IMyInterface.
    public static class Extension
    {
        public static void MethodA(this IMyInterface myInterface, int i)
        {
            Console.WriteLine
                ("Extension.MethodA(this IMyInterface myInterface, int i)");
        }

        public static void MethodA(this IMyInterface myInterface, string s)
        {
            Console.WriteLine
                ("Extension.MethodA(this IMyInterface myInterface, string s)");
        }

        // This method is never called in ExtensionMethodsDemo1, because each
        // of the three classes A, B, and C implements a method named MethodB
        // that has a matching signature.
        public static void MethodB(this IMyInterface myInterface)
        {
            Console.WriteLine
                ("Extension.MethodB(this IMyInterface myInterface)");
        }
    }
}
```

```

// Define three classes that implement IMyInterface, and then use them to test
// the extension methods.
namespace ExtensionMethodsDemo1
{
    using System;
    using Extensions;
    using DefineIMyInterface;

    class A : IMyInterface
    {
        public void MethodB() { Console.WriteLine("A.MethodB()"); }
    }

    class B : IMyInterface
    {
        public void MethodB() { Console.WriteLine("B.MethodB()"); }
        public void MethodA(int i) { Console.WriteLine("B.MethodA(int i)"); }
    }

    class C : IMyInterface
    {
        public void MethodB() { Console.WriteLine("C.MethodB()"); }
        public void MethodA(object obj)
        {
            Console.WriteLine("C.MethodA(object obj)");
        }
    }

    class ExtMethodDemo
    {
        static void Main(string[] args)
        {
            // Declare an instance of class A, class B, and class C.
            A a = new A();
            B b = new B();
            C c = new C();

            // For a, b, and c, call the following methods:
            //      -- MethodA with an int argument
            //      -- MethodA with a string argument
            //      -- MethodB with no argument.

            // A contains no MethodA, so each call to MethodA resolves to
            // the extension method that has a matching signature.
            a.MethodA(1);           // Extension.MethodA(IMyInterface, int)
            a.MethodA("hello");     // Extension.MethodA(IMyInterface, string)

            // A has a method that matches the signature of the following call
            // to MethodB.
            a.MethodB();           // A.MethodB()

            // B has methods that match the signatures of the following
            // method calls.
            b.MethodA(1);          // B.MethodA(int)
            b.MethodB();           // B.MethodB()

            // B has no matching method for the following call, but
            // class Extension does.
            b.MethodA("hello");    // Extension.MethodA(IMyInterface, string)

            // C contains an instance method that matches each of the following
            // method calls.
            c.MethodA(1);          // C.MethodA(object)
            c.MethodA("hello");    // C.MethodA(object)
            c.MethodB();           // C.MethodB()
        }
    }
}

```

```

s
/* Output:
    Extension.MethodA(this IMyInterface myInterface, int i)
    Extension.MethodA(this IMyInterface myInterface, string s)
    A.MethodB()
    B.MethodA(int i)
    B.MethodB()
    Extension.MethodA(this IMyInterface myInterface, string s)
    C.MethodA(object obj)
    C.MethodA(object obj)
    C.MethodB()
*/

```

Common Usage Patterns

Collection Functionality

In the past, it was common to create "Collection Classes" that implemented the [System.Collections.Generic.IEnumerable<T>](#) interface for a given type and contained functionality that acted on collections of that type. While there's nothing wrong with creating this type of collection object, the same functionality can be achieved by using an extension on the [System.Collections.Generic.IEnumerable<T>](#). Extensions have the advantage of allowing the functionality to be called from any collection such as an [System.Array](#) or [System.Collections.Generic.List<T>](#) that implements [System.Collections.Generic.IEnumerable<T>](#) on that type. An example of this using an Array of Int32 can be found [earlier in this article](#).

Layer-Specific Functionality

When using an Onion Architecture or other layered application design, it's common to have a set of Domain Entities or Data Transfer Objects that can be used to communicate across application boundaries. These objects generally contain no functionality, or only minimal functionality that applies to all layers of the application. Extension methods can be used to add functionality that is specific to each application layer without loading the object down with methods not needed or wanted in other layers.

```

public class DomainEntity
{
    public int Id { get; set; }
    public string FirstName { get; set; }
    public string LastName { get; set; }
}

static class DomainEntityExtensions
{
    static string FullName(this DomainEntity value)
        => $"{value.FirstName} {value.LastName}";
}

```

Extending Predefined Types

Rather than creating new objects when reusable functionality needs to be created, we can often extend an existing type, such as a .NET or CLR type. As an example, if we don't use extension methods, we might create an `Engine` or `Query` class to do the work of executing a query on a SQL Server that may be called from multiple places in our code. However we can instead extend the [System.Data.SqlClient.SqlConnection](#) class using extension methods to perform that query from anywhere we have a connection to a SQL Server. Other examples might be to add common functionality to the [System.String](#) class, extend the data processing capabilities of the [System.IO.File](#) and [System.IO.Stream](#) objects, and [System.Exception](#) objects for specific error handling functionality. These types of use-cases are limited only by your imagination and good sense.

Extending predefined types can be difficult with `struct` types because they're passed by value to methods. That means any changes to the struct are made to a copy of the struct. Those changes aren't visible once the

extension method exists. Beginning with C# 7.2, you can add the `ref` modifier to the first argument of an extension method. Adding the `ref` modifier means the first argument is passed by reference. This enables you to write extension methods that change the state of the struct being extended.

General Guidelines

While it's still considered preferable to add functionality by modifying an object's code or deriving a new type whenever it's reasonable and possible to do so, extension methods have become a crucial option for creating reusable functionality throughout the .NET ecosystem. For those occasions when the original source isn't under your control, when a derived object is inappropriate or impossible, or when the functionality shouldn't be exposed beyond its applicable scope, Extension methods are an excellent choice.

For more information on derived types, see [Inheritance](#).

When using an extension method to extend a type whose source code you aren't in control of, you run the risk that a change in the implementation of the type will cause your extension method to break.

If you do implement extension methods for a given type, remember the following points:

- An extension method will never be called if it has the same signature as a method defined in the type.
- Extension methods are brought into scope at the namespace level. For example, if you have multiple static classes that contain extension methods in a single namespace named `Extensions`, they'll all be brought into scope by the `using Extensions;` directive.

For a class library that you implemented, you shouldn't use extension methods to avoid incrementing the version number of an assembly. If you want to add significant functionality to a library for which you own the source code, follow the .NET guidelines for assembly versioning. For more information, see [Assembly Versioning](#).

How to implement and call a custom extension method (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

This topic shows how to implement your own extension methods for any .NET type. Client code can use your extension methods by adding a reference to the DLL that contains them, and adding a [using](#) directive that specifies the namespace in which the extension methods are defined.

To define and call the extension method

1. Define a static [class](#) to contain the extension method.

The class must be visible to client code. For more information about accessibility rules, see [Access Modifiers](#).

2. Implement the extension method as a static method with at least the same visibility as the containing class.
3. The first parameter of the method specifies the type that the method operates on; it must be preceded with the [this](#) modifier.
4. In the calling code, add a `using` directive to specify the [namespace](#) that contains the extension method class.
5. Call the methods as if they were instance methods on the type.

Note that the first parameter is not specified by calling code because it represents the type on which the operator is being applied, and the compiler already knows the type of your object. You only have to provide arguments for parameters 2 through `n`.

Example

The following example implements an extension method named `WordCount` in the `CustomExtensions.StringExtension` class. The method operates on the [String](#) class, which is specified as the first method parameter. The `CustomExtensions` namespace is imported into the application namespace, and the method is called inside the `Main` method.

```

using System.Linq;
using System.Text;
using System;

namespace CustomExtensions
{
    // Extension methods must be defined in a static class.
    public static class StringExtension
    {
        // This is the extension method.
        // The first parameter takes the "this" modifier
        // and specifies the type for which the method is defined.
        public static int WordCount(this String str)
        {
            return str.Split(new char[] { ' ', '.', '?' }, StringSplitOptions.RemoveEmptyEntries).Length;
        }
    }
}

namespace Extension_Methods_Simple
{
    // Import the extension method namespace.
    using CustomExtensions;
    class Program
    {
        static void Main(string[] args)
        {
            string s = "The quick brown fox jumped over the lazy dog.";
            // Call the method as if it were an
            // instance method on the type. Note that the first
            // parameter is not specified by the calling code.
            int i = s.WordCount();
            System.Console.WriteLine("Word count of s is {0}", i);
        }
    }
}

```

.NET Security

Extension methods present no specific security vulnerabilities. They can never be used to impersonate existing methods on a type, because all name collisions are resolved in favor of the instance or static method defined by the type itself. Extension methods cannot access any private data in the extended class.

How to create a new method for an enumeration (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

You can use extension methods to add functionality specific to a particular enum type.

Example

In the following example, the `Grades` enumeration represents the possible letter grades that a student may receive in a class. An extension method named `Passing` is added to the `Grades` type so that each instance of that type now "knows" whether it represents a passing grade or not.

```
using System;
using System.Collections.Generic;
using System.Text;
using System.Linq;

namespace EnumExtension
{
    // Define an extension method in a non-nested static class.
    public static class Extensions
    {
        public static Grades minPassing = Grades.D;
        public static bool Passing(this Grades grade)
        {
            return grade >= minPassing;
        }
    }

    public enum Grades { F = 0, D=1, C=2, B=3, A=4 };
    class Program
    {
        static void Main(string[] args)
        {
            Grades g1 = Grades.D;
            Grades g2 = Grades.F;
            Console.WriteLine("First {0} a passing grade.", g1.Passing() ? "is" : "is not");
            Console.WriteLine("Second {0} a passing grade.", g2.Passing() ? "is" : "is not");

            Extensions.minPassing = Grades.C;
            Console.WriteLine("\r\nRaising the bar!\r\n");
            Console.WriteLine("First {0} a passing grade.", g1.Passing() ? "is" : "is not");
            Console.WriteLine("Second {0} a passing grade.", g2.Passing() ? "is" : "is not");
        }
    }
}

/* Output:
First is a passing grade.
Second is not a passing grade.

Raising the bar!

First is not a passing grade.
Second is not a passing grade.
*/
```

Note that the `Extensions` class also contains a static variable that is updated dynamically and that the return

value of the extension method reflects the current value of that variable. This demonstrates that, behind the scenes, extension methods are invoked directly on the static class in which they are defined.

Named and Optional Arguments (C# Programming Guide)

12/28/2021 • 7 minutes to read • [Edit Online](#)

C# 4 introduces named and optional arguments. *Named arguments* enable you to specify an argument for a parameter by matching the argument with its name rather than with its position in the parameter list. *Optional arguments* enable you to omit arguments for some parameters. Both techniques can be used with methods, indexers, constructors, and delegates.

When you use named and optional arguments, the arguments are evaluated in the order in which they appear in the argument list, not the parameter list.

Named and optional parameters enable you to supply arguments for selected parameters. This capability greatly eases calls to COM interfaces such as the Microsoft Office Automation APIs.

Named arguments

Named arguments free you from matching the order of parameters in the parameter lists of called methods. The parameter for each argument can be specified by parameter name. For example, a function that prints order details (such as, seller name, order number & product name) can be called by sending arguments by position, in the order defined by the function.

```
PrintOrderDetails("Gift Shop", 31, "Red Mug");
```

If you don't remember the order of the parameters but know their names, you can send the arguments in any order.

```
PrintOrderDetails(orderNum: 31, productName: "Red Mug", sellerName: "Gift Shop");  
PrintOrderDetails(productName: "Red Mug", sellerName: "Gift Shop", orderNum: 31);
```

Named arguments also improve the readability of your code by identifying what each argument represents. In the example method below, the `sellerName` can't be null or white space. As both `sellerName` and `productName` are string types, instead of sending arguments by position, it makes sense to use named arguments to disambiguate the two and reduce confusion for anyone reading the code.

Named arguments, when used with positional arguments, are valid as long as

- they're not followed by any positional arguments, or

```
PrintOrderDetails("Gift Shop", 31, productName: "Red Mug");
```

- *starting with C# 7.2*, they're used in the correct position. In the example below, the parameter `orderNum` is in the correct position but isn't explicitly named.

```
PrintOrderDetails(sellerName: "Gift Shop", 31, productName: "Red Mug");
```

Positional arguments that follow any out-of-order named arguments are invalid.

```
// This generates CS1738: Named argument specifications must appear after all fixed arguments have been
specified.
PrintOrderDetails(productName: "Red Mug", 31, "Gift Shop");
```

Example

The following code implements the examples from this section along with some additional ones.

```
class NamedExample
{
    static void Main(string[] args)
    {
        // The method can be called in the normal way, by using positional arguments.
        PrintOrderDetails("Gift Shop", 31, "Red Mug");

        // Named arguments can be supplied for the parameters in any order.
        PrintOrderDetails(orderNum: 31, productName: "Red Mug", sellerName: "Gift Shop");
        PrintOrderDetails(productName: "Red Mug", sellerName: "Gift Shop", orderNum: 31);

        // Named arguments mixed with positional arguments are valid
        // as long as they are used in their correct position.
        PrintOrderDetails("Gift Shop", 31, productName: "Red Mug");
        PrintOrderDetails(sellerName: "Gift Shop", 31, productName: "Red Mug");    // C# 7.2 onwards
        PrintOrderDetails("Gift Shop", orderNum: 31, "Red Mug");                // C# 7.2 onwards

        // However, mixed arguments are invalid if used out-of-order.
        // The following statements will cause a compiler error.
        // PrintOrderDetails(productName: "Red Mug", 31, "Gift Shop");
        // PrintOrderDetails(31, sellerName: "Gift Shop", "Red Mug");
        // PrintOrderDetails(31, "Red Mug", sellerName: "Gift Shop");
    }

    static void PrintOrderDetails(string sellerName, int orderNum, string productName)
    {
        if (string.IsNullOrEmpty(sellerName))
        {
            throw new ArgumentException(message: "Seller name cannot be null or empty.", paramName:
nameof(sellerName));
        }

        Console.WriteLine($"Seller: {sellerName}, Order #: {orderNum}, Product: {productName}");
    }
}
```

Optional arguments

The definition of a method, constructor, indexer, or delegate can specify its parameters are required or optional. Any call must provide arguments for all required parameters, but can omit arguments for optional parameters.

Each optional parameter has a default value as part of its definition. If no argument is sent for that parameter, the default value is used. A default value must be one of the following types of expressions:

- a constant expression;
- an expression of the form `new ValType()`, where `ValType` is a value type, such as an [enum](#) or a [struct](#);
- an expression of the form `default(ValType)`, where `ValType` is a value type.

Optional parameters are defined at the end of the parameter list, after any required parameters. If the caller provides an argument for any one of a succession of optional parameters, it must provide arguments for all preceding optional parameters. Comma-separated gaps in the argument list aren't supported. For example, in the following code, instance method `ExampleMethod` is defined with one required and two optional parameters.

```
public void ExampleMethod(int required, string optionalstr = "default string",
    int optionalint = 10)
```

The following call to `ExampleMethod` causes a compiler error, because an argument is provided for the third parameter but not for the second.

```
//anExample.ExampleMethod(3, ,4);
```

However, if you know the name of the third parameter, you can use a named argument to accomplish the task.

```
anExample.ExampleMethod(3, optionalint: 4);
```

IntelliSense uses brackets to indicate optional parameters, as shown in the following illustration:

```
anExample.ExampleMethod(  
    void ExampleClass.ExampleMethod(int required,  
        [string optionalstr = "default string"],  
        [int optionalint = 10])
```

NOTE

You can also declare optional parameters by using the .NET [OptionalAttribute](#) class. `OptionalAttribute` parameters do not require a default value.

Example

In the following example, the constructor for `ExampleClass` has one parameter, which is optional. Instance method `ExampleMethod` has one required parameter, `required`, and two optional parameters, `optionalstr` and `optionalint`. The code in `Main` shows the different ways in which the constructor and method can be invoked.

```
namespace OptionalNamespace
{
    class OptionalExample
    {
        static void Main(string[] args)
        {
            // Instance anExample does not send an argument for the constructor's
            // optional parameter.
            ExampleClass anExample = new ExampleClass();
            anExample.ExampleMethod(1, "One", 1);
            anExample.ExampleMethod(2, "Two");
            anExample.ExampleMethod(3);

            // Instance anotherExample sends an argument for the constructor's
            // optional parameter.
            ExampleClass anotherExample = new ExampleClass("Provided name");
            anotherExample.ExampleMethod(1, "One", 1);
            anotherExample.ExampleMethod(2, "Two");
            anotherExample.ExampleMethod(3);

            // The following statements produce compiler errors.

            // An argument must be supplied for the first parameter, and it
            // must be an integer.
            //anExample.ExampleMethod("One", 1);
            //anExample.ExampleMethod();

            // You cannot leave a gap in the provided arguments.
            //anExample.ExampleMethod(3, ,4);
```

```

        //anExample.ExampleMethod(3, 4);

        // You can use a named parameter to make the previous
        // statement work.
        anExample.ExampleMethod(3, optionalint: 4);
    }
}

class ExampleClass
{
    private string _name;

    // Because the parameter for the constructor, name, has a default
    // value assigned to it, it is optional.
    public ExampleClass(string name = "Default name")
    {
        _name = name;
    }

    // The first parameter, required, has no default value assigned
    // to it. Therefore, it is not optional. Both optionalstr and
    // optionalint have default values assigned to them. They are optional.
    public void ExampleMethod(int required, string optionalstr = "default string",
        int optionalint = 10)
    {
        Console.WriteLine(
            $"{_name}: {required}, {optionalstr}, and {optionalint}.");
    }
}

// The output from this example is the following:
// Default name: 1, One, and 1.
// Default name: 2, Two, and 10.
// Default name: 3, default string, and 10.
// Provided name: 1, One, and 1.
// Provided name: 2, Two, and 10.
// Provided name: 3, default string, and 10.
// Default name: 3, default string, and 4.
}

```

The preceding code shows a number of examples where optional parameters aren't applied correctly. The first illustrates that an argument must be supplied for the first parameter, which is required.

COM interfaces

Named and optional arguments, along with support for dynamic objects, greatly improve interoperability with COM APIs, such as Office Automation APIs.

For example, the [AutoFormat](#) method in the Microsoft Office Excel [Range](#) interface has seven parameters, all of which are optional. These parameters are shown in the following illustration:

```

excelApp.get_Range("A1", "B4").AutoFormat(
    dynamic Range.AutoFormat([Excel.XlRangeAutoFormat Format = 1],
        [object Number = Type.Missing], [object Font = Type.Missing],
        [object Alignment = Type.Missing], [object Border = Type.Missing],
        [object Pattern = Type.Missing], [object Width = Type.Missing])

```

In C# 3.0 and earlier versions, an argument is required for each parameter, as shown in the following example.

```
// In C# 3.0 and earlier versions, you need to supply an argument for
// every parameter. The following call specifies a value for the first
// parameter, and sends a placeholder value for the other six. The
// default values are used for those parameters.
var excelApp = new Microsoft.Office.Interop.Excel.Application();
excelApp.Workbooks.Add();
excelApp.Visible = true;

var myFormat =
    Microsoft.Office.Interop.Excel.XlRangeAutoFormat.xlRangeAutoFormatAccounting1;

excelApp.get_Range("A1", "B4").AutoFormat(myFormat, Type.Missing,
    Type.Missing, Type.Missing, Type.Missing, Type.Missing, Type.Missing);
```

However, you can greatly simplify the call to `AutoFormat` by using named and optional arguments, introduced in C# 4.0. Named and optional arguments enable you to omit the argument for an optional parameter if you don't want to change the parameter's default value. In the following call, a value is specified for only one of the seven parameters.

```
// The following code shows the same call to AutoFormat in C# 4.0. Only
// the argument for which you want to provide a specific value is listed.
excelApp.Range["A1", "B4"].AutoFormat( Format: myFormat );
```

For more information and examples, see [How to use named and optional arguments in Office programming](#) and [How to access Office interop objects by using C# features](#).

Overload resolution

Use of named and optional arguments affects overload resolution in the following ways:

- A method, indexer, or constructor is a candidate for execution if each of its parameters either is optional or corresponds, by name or by position, to a single argument in the calling statement, and that argument can be converted to the type of the parameter.
- If more than one candidate is found, overload resolution rules for preferred conversions are applied to the arguments that are explicitly specified. Omitted arguments for optional parameters are ignored.
- If two candidates are judged to be equally good, preference goes to a candidate that doesn't have optional parameters for which arguments were omitted in the call. Overload resolution generally prefers candidates that have fewer parameters.

C# language specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

How to use named and optional arguments in Office programming (C# Programming Guide)

12/28/2021 • 5 minutes to read • [Edit Online](#)

Named arguments and optional arguments, introduced in C# 4, enhance convenience, flexibility, and readability in C# programming. In addition, these features greatly facilitate access to COM interfaces such as the Microsoft Office automation APIs.

In the following example, method [ConvertToTable](#) has sixteen parameters that represent characteristics of a table, such as number of columns and rows, formatting, borders, fonts, and colors. All sixteen parameters are optional, because most of the time you do not want to specify particular values for all of them. However, without named and optional arguments, a value or a placeholder value has to be provided for each parameter. With named and optional arguments, you specify values only for the parameters that are required for your project.

You must have Microsoft Office Word installed on your computer to complete these procedures.

NOTE

Your computer might show different names or locations for some of the Visual Studio user interface elements in the following instructions. The Visual Studio edition that you have and the settings that you use determine these elements. For more information, see [Personalizing the IDE](#).

To create a new console application

1. Start Visual Studio.
2. On the **File** menu, point to **New**, and then click **Project**.
3. In the **Templates Categories** pane, expand **Visual C#**, and then click **Windows**.
4. Look in the top of the **Templates** pane to make sure that **.NET Framework 4** appears in the **Target Framework** box.
5. In the **Templates** pane, click **Console Application**.
6. Type a name for your project in the **Name** field.
7. Click **OK**.

The new project appears in **Solution Explorer**.

To add a reference

1. In **Solution Explorer**, right-click your IDE project's name and then click **Add Reference**. The **Add Reference** dialog box appears.
2. On the **.NET** page, select **Microsoft.Office.Interop.Word** in the **Component Name** list.
3. Click **OK**.

To add necessary using directives

1. In **Solution Explorer**, right-click the *Program.cs* file and then click **View Code**.

2. Add the following `using` directives to the top of the code file:

```
using Word = Microsoft.Office.Interop.Word;
```

To display text in a Word document

1. In the `Program` class in *Program.cs*, add the following method to create a Word application and a Word document. The `Add` method has four optional parameters. This example uses their default values. Therefore, no arguments are necessary in the calling statement.

```
static void DisplayInWord()
{
    var wordApp = new Word.Application();
    wordApp.Visible = true;
    // docs is a collection of all the Document objects currently
    // open in Word.
    Word.Documents docs = wordApp.Documents;

    // Add a document to the collection and name it doc.
    Word.Document doc = docs.Add();
}
```

2. Add the following code at the end of the method to define where to display text in the document, and what text to display:

```
// Define a range, a contiguous area in the document, by specifying
// a starting and ending character position. Currently, the document
// is empty.
Word.Range range = doc.Range(0, 0);

// Use the InsertAfter method to insert a string at the end of the
// current range.
range.InsertAfter("Testing, testing, testing. . .");
```

To run the application

1. Add the following statement to `Main`:

```
DisplayInWord();
```

2. Press CTRL+F5 to run the project. A Word document appears that contains the specified text.

To change the text to a table

1. Use the `ConvertToTable` method to enclose the text in a table. The method has sixteen optional parameters. IntelliSense encloses optional parameters in brackets, as shown in the following illustration.

```
range.ConvertToTable(|
Word.Table Range.ConvertToTable([ref object Separator = Type.Missing], [ref object NumRows =
Type.Missing], [ref object NumColumns = Type.Missing], [ref object InitialColumnWidth =
Type.Missing], [ref object Format = Type.Missing], [ref object ApplyBorders = Type.Missing],
[ref object ApplyShading = Type.Missing], [ref object ApplyFont = Type.Missing], [ref object
ApplyColor = Type.Missing], [ref object ApplyHeadingsRows = Type.Missing], [ref object
ApplyLastRow = Type.Missing], [ref object ApplyFirstColumn = Type.Missing], [ref object
ApplyLastColumn = Type.Missing], [ref object AutoFit = Type.Missing], [ref object
AutoFitBehavior = Type.Missing], [ref object DefaultTableBehavior = Type.Missing])
```

Named and optional arguments enable you to specify values for only the parameters that you want to change. Add the following code to the end of method `DisplayInWord` to create a simple table. The argument specifies that the commas in the text string in `range` separate the cells of the table.

```
// Convert to a simple table. The table will have a single row with
// three columns.
range.ConvertToTable(Separator: ",");
```

In earlier versions of C#, the call to `ConvertToTable` requires a reference argument for each parameter, as shown in the following code:

```
// Call to ConvertToTable in Visual C# 2008 or earlier. This code
// is not part of the solution.
var missing = Type.Missing;
object separator = ",";
range.ConvertToTable(ref separator, ref missing, ref missing,
    ref missing, ref missing, ref missing, ref missing,
    ref missing, ref missing, ref missing, ref missing,
    ref missing);
```

2. Press CTRL+F5 to run the project.

To experiment with other parameters

1. To change the table so that it has one column and three rows, replace the last line in `DisplayInWord` with the following statement and then type CTRL+F5.

```
range.ConvertToTable(Separator: ",", AutoFit: true, NumColumns: 1);
```

2. To specify a predefined format for the table, replace the last line in `DisplayInWord` with the following statement and then type CTRL+F5. The format can be any of the [WdTableFormat](#) constants.

```
range.ConvertToTable(Separator: ",", AutoFit: true, NumColumns: 1,
    Format: Word.WdTableFormat.wdTableFormatElegant);
```

Example

The following code includes the full example:

```

using System;
using System.Collections.Generic;
using System.Linq;
using System.Text;
using Word = Microsoft.Office.Interop.Word;

namespace OfficeHowTo
{
    class WordProgram
    {
        static void Main(string[] args)
        {
            DisplayInWord();
        }

        static void DisplayInWord()
        {
            var wordApp = new Word.Application();
            wordApp.Visible = true;
            // docs is a collection of all the Document objects currently
            // open in Word.
            Word.Documents docs = wordApp.Documents;

            // Add a document to the collection and name it doc.
            Word.Document doc = docs.Add();

            // Define a range, a contiguous area in the document, by specifying
            // a starting and ending character position. Currently, the document
            // is empty.
            Word.Range range = doc.Range(0, 0);

            // Use the InsertAfter method to insert a string at the end of the
            // current range.
            range.InsertAfter("Testing, testing, testing. .");

            // You can comment out any or all of the following statements to
            // see the effect of each one in the Word document.

            // Next, use the ConvertToTable method to put the text into a table.
            // The method has 16 optional parameters. You only have to specify
            // values for those you want to change.

            // Convert to a simple table. The table will have a single row with
            // three columns.
            range.ConvertToTable(Separator: ",");

            // Change to a single column with three rows..
            range.ConvertToTable(Separator: ",", AutoFit: true, NumColumns: 1);

            // Format the table.
            range.ConvertToTable(Separator: ",", AutoFit: true, NumColumns: 1,
                                Format: Word.WdTableFormat.wdTableFormatElegant);
        }
    }
}

```

Constructors (C# programming guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Whenever a [class](#) or [struct](#) is created, its constructor is called. A class or struct may have multiple constructors that take different arguments. Constructors enable the programmer to set default values, limit instantiation, and write code that is flexible and easy to read. For more information and examples, see [Instance constructors](#) and [Using constructors](#).

Constructor syntax

A constructor is a method whose name is the same as the name of its type. Its method signature includes only the method name and its parameter list; it does not include a return type. The following example shows the constructor for a class named `Person`.

```
public class Person
{
    private string last;
    private string first;

    public Person(string lastName, string firstName)
    {
        last = lastName;
        first = firstName;
    }

    // Remaining implementation of Person class.
}
```

If a constructor can be implemented as a single statement, you can use an [expression body definition](#). The following example defines a `Location` class whose constructor has a single string parameter named *name*. The expression body definition assigns the argument to the `locationName` field.

```
public class Location
{
    private string locationName;

    public Location(string name) => Name = name;

    public string Name
    {
        get => locationName;
        set => locationName = value;
    }
}
```

Static constructors

The previous examples have all shown instance constructors, which create a new object. A class or struct can also have a static constructor, which initializes static members of the type. Static constructors are parameterless. If you don't provide a static constructor to initialize static fields, the C# compiler initializes static fields to their default value as listed in the [Default values of C# types](#) article.

The following example uses a static constructor to initialize a static field.

```

public class Adult : Person
{
    private static int minimumAge;

    public Adult(string lastName, string firstName) : base(lastName, firstName)
    { }

    static Adult()
    {
        minimumAge = 18;
    }

    // Remaining implementation of Adult class.
}

```

You can also define a static constructor with an expression body definition, as the following example shows.

```

public class Child : Person
{
    private static int maximumAge;

    public Child(string lastName, string firstName) : base(lastName, firstName)
    { }

    static Child() => maximumAge = 18;

    // Remaining implementation of Child class.
}

```

For more information and examples, see [Static Constructors](#).

Using Constructors (C# Programming Guide)

12/28/2021 • 4 minutes to read • [Edit Online](#)

When a [class](#) or [struct](#) is created, its constructor is called. Constructors have the same name as the class or struct, and they usually initialize the data members of the new object.

In the following example, a class named `Taxi` is defined by using a simple constructor. This class is then instantiated with the [new](#) operator. The `Taxi` constructor is invoked by the `new` operator immediately after memory is allocated for the new object.

```
public class Taxi
{
    public bool IsInitialized;

    public Taxi()
    {
        IsInitialized = true;
    }
}

class TestTaxi
{
    static void Main()
    {
        Taxi t = new Taxi();
        Console.WriteLine(t.IsInitialized);
    }
}
```

A constructor that takes no parameters is called a *parameterless constructor*. Parameterless constructors are invoked whenever an object is instantiated by using the `new` operator and no arguments are provided to `new`. For more information, see [Instance Constructors](#).

Unless the class is [static](#), classes without constructors are given a public parameterless constructor by the C# compiler in order to enable class instantiation. For more information, see [Static Classes and Static Class Members](#).

You can prevent a class from being instantiated by making the constructor private, as follows:

```
class NLog
{
    // Private Constructor:
    private NLog() { }

    public static double e = Math.E; //2.71828...
}
```

For more information, see [Private Constructors](#).

Constructors for [struct](#) types resemble class constructors, but `structs` cannot contain an explicit parameterless constructor because one is provided automatically by the compiler. This constructor initializes each field in the `struct` to the [default value](#). However, this parameterless constructor is only invoked if the `struct` is instantiated with `new`. For example, this code uses the parameterless constructor for [Int32](#), so that you are assured that the integer is initialized:

```
int i = new int();
Console.WriteLine(i);
```

NOTE

Beginning with C# 10, a structure type can contain an explicit parameterless constructor. For more information, see the [Parameterless constructors and field initializers](#) section of the [Structure types](#) article.

The following code, however, causes a compiler error because it does not use `new`, and because it tries to use an object that has not been initialized:

```
int i;
Console.WriteLine(i);
```

Alternatively, objects based on `structs` (including all built-in numeric types) can be initialized or assigned and then used as in the following example:

```
int a = 44; // Initialize the value type...
int b;
b = 33;     // Or assign it before using it.
Console.WriteLine("{0}, {1}", a, b);
```

So calling the parameterless constructor for a value type is not required.

Both classes and `structs` can define constructors that take parameters. Constructors that take parameters must be called through a `new` statement or a `base` statement. Classes and `structs` can also define multiple constructors, and neither is required to define a parameterless constructor. For example:

```
public class Employee
{
    public int Salary;

    public Employee() { }

    public Employee(int annualSalary)
    {
        Salary = annualSalary;
    }

    public Employee(int weeklySalary, int numberOfWeeks)
    {
        Salary = weeklySalary * numberOfWeeks;
    }
}
```

This class can be created by using either of the following statements:

```
Employee e1 = new Employee(30000);
Employee e2 = new Employee(500, 52);
```

A constructor can use the `base` keyword to call the constructor of a base class. For example:

```
public class Manager : Employee
{
    public Manager(int annualSalary)
        : base(annualSalary)
    {
        //Add further instructions here.
    }
}
```

In this example, the constructor for the base class is called before the block for the constructor is executed. The `base` keyword can be used with or without parameters. Any parameters to the constructor can be used as parameters to `base`, or as part of an expression. For more information, see [base](#).

In a derived class, if a base-class constructor is not called explicitly by using the `base` keyword, the parameterless constructor, if there is one, is called implicitly. This means that the following constructor declarations are effectively the same:

```
public Manager(int initialData)
{
    //Add further instructions here.
}
```

```
public Manager(int initialData)
    : base()
{
    //Add further instructions here.
}
```

If a base class does not offer a parameterless constructor, the derived class must make an explicit call to a base constructor by using `base`.

A constructor can invoke another constructor in the same object by using the `this` keyword. Like `base`, `this` can be used with or without parameters, and any parameters in the constructor are available as parameters to `this`, or as part of an expression. For example, the second constructor in the previous example can be rewritten using `this`:

```
public Employee(int weeklySalary, int numberOfWeeks)
    : this(weeklySalary * numberOfWeeks)
{
}
```

The use of the `this` keyword in the previous example causes this constructor to be called:

```
public Employee(int annualSalary)
{
    Salary = annualSalary;
}
```

Constructors can be marked as [public](#), [private](#), [protected](#), [internal](#), [protected internal](#) or [private protected](#). These access modifiers define how users of the class can construct the class. For more information, see [Access Modifiers](#).

A constructor can be declared static by using the [static](#) keyword. Static constructors are called automatically, immediately before any static fields are accessed, and are generally used to initialize static class members. For more information, see [Static Constructors](#).

C# Language Specification

For more information, see [Instance constructors](#) and [Static constructors](#) in the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

Instance constructors (C# programming guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

You declare an instance constructor to specify the code that is executed when you create a new instance of a type with the `new` expression. To initialize a `static` class or static variables in a non-static class, you can define a `static constructor`.

As the following example shows, you can declare several instance constructors in one type:

```
using System;

class Coords
{
    public Coords()
        : this(0, 0)
    { }

    public Coords(int x, int y)
    {
        X = x;
        Y = y;
    }

    public int X { get; set; }
    public int Y { get; set; }

    public override string ToString() => $"({X},{Y})";
}

class Example
{
    static void Main()
    {
        var p1 = new Coords();
        Console.WriteLine($"Coords #1 at {p1}");
        // Output: Coords #1 at (0,0)

        var p2 = new Coords(5, 3);
        Console.WriteLine($"Coords #2 at {p2}");
        // Output: Coords #2 at (5,3)
    }
}
```

In the preceding example, the first, parameterless, constructor calls the second constructor with both arguments equal `0`. To do that, use the `this` keyword.

When you declare an instance constructor in a derived class, you can call a constructor of a base class. To do that, use the `base` keyword, as the following example shows:

```

using System;

abstract class Shape
{
    public const double pi = Math.PI;
    protected double x, y;

    public Shape(double x, double y)
    {
        this.x = x;
        this.y = y;
    }

    public abstract double Area();
}

class Circle : Shape
{
    public Circle(double radius)
        : base(radius, 0)
    { }

    public override double Area() => pi * x * x;
}

class Cylinder : Circle
{
    public Cylinder(double radius, double height)
        : base(radius)
    {
        y = height;
    }

    public override double Area() => (2 * base.Area()) + (2 * pi * x * y);
}

class Example
{
    static void Main()
    {
        double radius = 2.5;
        double height = 3.0;

        var ring = new Circle(radius);
        Console.WriteLine($"Area of the circle = {ring.Area():F2}");
        // Output: Area of the circle = 19.63

        var tube = new Cylinder(radius, height);
        Console.WriteLine($"Area of the cylinder = {tube.Area():F2}");
        // Output: Area of the cylinder = 86.39
    }
}

```

Parameterless constructors

If a *class* has no explicit instance constructors, C# provides a parameterless constructor that you can use to instantiate an instance of that class, as the following example shows:

```

using System;

public class Person
{
    public int age;
    public string name = "unknown";
}

class Example
{
    static void Main()
    {
        var person = new Person();
        Console.WriteLine($"Name: {person.name}, Age: {person.age}");
        // Output: Name: unknown, Age: 0
    }
}

```

That constructor initializes instance fields and properties according to the corresponding initializers. If a field or property has no initializer, its value is set to the [default value](#) of the field's or property's type. If you declare at least one instance constructor in a class, C# doesn't provide a parameterless constructor.

A *structure* type always provides a parameterless constructor as follows:

- In C# 9.0 and earlier, that is an implicit parameterless constructor that produces the [default value](#) of a type.
- In C# 10 and later, that is either an implicit parameterless constructor that produces the default value of a type or an explicitly declared parameterless constructor. For more information, see the [Parameterless constructors and field initializers](#) section of the [Structure types](#) article.

Private Constructors (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

A private constructor is a special instance constructor. It is generally used in classes that contain static members only. If a class has one or more private constructors and no public constructors, other classes (except nested classes) cannot create instances of this class. For example:

```
class NLog
{
    // Private Constructor:
    private NLog() { }

    public static double e = Math.E; //2.71828...
}
```

The declaration of the empty constructor prevents the automatic generation of a parameterless constructor. Note that if you do not use an access modifier with the constructor it will still be private by default. However, the [private](#) modifier is usually used explicitly to make it clear that the class cannot be instantiated.

Private constructors are used to prevent creating instances of a class when there are no instance fields or methods, such as the [Math](#) class, or when a method is called to obtain an instance of a class. If all the methods in the class are static, consider making the complete class static. For more information see [Static Classes and Static Class Members](#).

Example

The following is an example of a class using a private constructor.

```

public class Counter
{
    private Counter() { }

    public static int currentCount;

    public static int IncrementCount()
    {
        return ++currentCount;
    }
}

class TestCounter
{
    static void Main()
    {
        // If you uncomment the following statement, it will generate
        // an error because the constructor is inaccessible:
        // Counter aCounter = new Counter();    // Error

        Counter.currentCount = 100;
        Counter.IncrementCount();
        Console.WriteLine("New count: {0}", Counter.currentCount);

        // Keep the console window open in debug mode.
        Console.WriteLine("Press any key to exit.");
        Console.ReadKey();
    }
}
// Output: New count: 101

```

Notice that if you uncomment the following statement from the example, it will generate an error because the constructor is inaccessible because of its protection level:

```

// Counter aCounter = new Counter();    // Error

```

C# Language Specification

For more information, see [Private constructors](#) in the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

Static Constructors (C# Programming Guide)

12/28/2021 • 4 minutes to read • [Edit Online](#)

A static constructor is used to initialize any [static](#) data, or to perform a particular action that needs to be performed only once. It is called automatically before the first instance is created or any static members are referenced.

```
class SimpleClass
{
    // Static variable that must be initialized at run time.
    static readonly long baseline;

    // Static constructor is called at most one time, before any
    // instance constructor is invoked or member is accessed.
    static SimpleClass()
    {
        baseline = DateTime.Now.Ticks;
    }
}
```

Remarks

Static constructors have the following properties:

- A static constructor doesn't take access modifiers or have parameters.
- A class or struct can only have one static constructor.
- Static constructors cannot be inherited or overloaded.
- A static constructor cannot be called directly and is only meant to be called by the common language runtime (CLR). It is invoked automatically.
- The user has no control on when the static constructor is executed in the program.
- A static constructor is called automatically. It initializes the [class](#) before the first instance is created or any static members declared in that class (not its base classes) are referenced. A static constructor runs before an instance constructor. A type's static constructor is called when a static method assigned to an event or a delegate is invoked and not when it is assigned. If static field variable initializers are present in the class of the static constructor, they're executed in the textual order in which they appear in the class declaration. The initializers run immediately prior to the execution of the static constructor.
- If you don't provide a static constructor to initialize static fields, all static fields are initialized to their default value as listed in [Default values of C# types](#).
- If a static constructor throws an exception, the runtime doesn't invoke it a second time, and the type will remain uninitialized for the lifetime of the application domain. Most commonly, a [TypeInitializationException](#) exception is thrown when a static constructor is unable to instantiate a type or for an unhandled exception occurring within a static constructor. For static constructors that aren't explicitly defined in source code, troubleshooting may require inspection of the intermediate language (IL) code.
- The presence of a static constructor prevents the addition of the [BeforeFieldInit](#) type attribute. This limits runtime optimization.
- A field declared as `static readonly` may only be assigned as part of its declaration or in a static constructor. When an explicit static constructor isn't required, initialize static fields at declaration rather than through a static constructor for better runtime optimization.
- The runtime calls a static constructor no more than once in a single application domain. That call is made in a locked region based on the specific type of the class. No additional locking mechanisms are needed in the

body of a static constructor. To avoid the risk of deadlocks, don't block the current thread in static constructors and initializers. For example, don't wait on tasks, threads, wait handles or events, don't acquire locks, and don't execute blocking parallel operations such as parallel loops, `Parallel.Invoke` and Parallel LINQ queries.

NOTE

Though not directly accessible, the presence of an explicit static constructor should be documented to assist with troubleshooting initialization exceptions.

Usage

- A typical use of static constructors is when the class is using a log file and the constructor is used to write entries to this file.
- Static constructors are also useful when creating wrapper classes for unmanaged code, when the constructor can call the `LoadLibrary` method.
- Static constructors are also a convenient place to enforce run-time checks on the type parameter that cannot be checked at compile time via type-parameter constraints.

Example

In this example, class `Bus` has a static constructor. When the first instance of `Bus` is created (`bus1`), the static constructor is invoked to initialize the class. The sample output verifies that the static constructor runs only one time, even though two instances of `Bus` are created, and that it runs before the instance constructor runs.

```
public class Bus
{
    // Static variable used by all Bus instances.
    // Represents the time the first bus of the day starts its route.
    protected static readonly DateTime globalStartTime;

    // Property for the number of each bus.
    protected int RouteNumber { get; set; }

    // Static constructor to initialize the static variable.
    // It is invoked before the first instance constructor is run.
    static Bus()
    {
        globalStartTime = DateTime.Now;

        // The following statement produces the first line of output,
        // and the line occurs only once.
        Console.WriteLine("Static constructor sets global start time to {0}",
            globalStartTime.ToLongTimeString());
    }

    // Instance constructor.
    public Bus(int routeNum)
    {
        RouteNumber = routeNum;
        Console.WriteLine("Bus #{0} is created.", RouteNumber);
    }

    // Instance method.
    public void Drive()
    {
        TimeSpan elapsedTime = DateTime.Now - globalStartTime;

        // For demonstration purposes we treat milliseconds as minutes to simulate
        // actual bus times. Do not do this in your actual bus schedule program!
        Console.WriteLine("{0} is starting its route {1:N2} minutes after global start time {2}.",
```

```

        this.RouteNumber,
        elapsedTime.Milliseconds,
        globalStartTime.ToShortTimeString());
    }
}

class TestBus
{
    static void Main()
    {
        // The creation of this instance activates the static constructor.
        Bus bus1 = new Bus(71);

        // Create a second bus.
        Bus bus2 = new Bus(72);

        // Send bus1 on its way.
        bus1.Drive();

        // Wait for bus2 to warm up.
        System.Threading.Thread.Sleep(25);

        // Send bus2 on its way.
        bus2.Drive();

        // Keep the console window open in debug mode.
        Console.WriteLine("Press any key to exit.");
        Console.ReadKey();
    }
}

/* Sample output:
    Static constructor sets global start time to 3:57:08 PM.
    Bus #71 is created.
    Bus #72 is created.
    71 is starting its route 6.00 minutes after global start time 3:57 PM.
    72 is starting its route 31.00 minutes after global start time 3:57 PM.
*/

```

How to write a copy constructor (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

C# [records](#) provide a copy constructor for objects, but for classes you have to write one yourself.

Example

In the following example, the `Person` class defines a copy constructor that takes, as its argument, an instance of `Person`. The values of the properties of the argument are assigned to the properties of the new instance of `Person`. The code contains an alternative copy constructor that sends the `Name` and `Age` properties of the instance that you want to copy to the instance constructor of the class.

```

using System;

class Person
{
    // Copy constructor.
    public Person(Person previousPerson)
    {
        Name = previousPerson.Name;
        Age = previousPerson.Age;
    }

    //// Alternate copy constructor calls the instance constructor.
    //public Person(Person previousPerson)
    //    : this(previousPerson.Name, previousPerson.Age)
    //{
    //}

    // Instance constructor.
    public Person(string name, int age)
    {
        Name = name;
        Age = age;
    }

    public int Age { get; set; }

    public string Name { get; set; }

    public string Details()
    {
        return Name + " is " + Age.ToString();
    }
}

class TestPerson
{
    static void Main()
    {
        // Create a Person object by using the instance constructor.
        Person person1 = new Person("George", 40);

        // Create another Person object, copying person1.
        Person person2 = new Person(person1);

        // Change each person's age.
        person1.Age = 39;
        person2.Age = 41;

        // Change person2's name.
        person2.Name = "Charles";

        // Show details to verify that the name and age fields are distinct.
        Console.WriteLine(person1.Details());
        Console.WriteLine(person2.Details());

        // Keep the console window open in debug mode.
        Console.WriteLine("Press any key to exit.");
        Console.ReadKey();
    }
}

// Output:
// George is 39
// Charles is 41

```

- [Finalizers](#)

Finalizers (C# Programming Guide)

12/28/2021 • 4 minutes to read • [Edit Online](#)

Finalizers (historically referred to as **destructors**) are used to perform any necessary final clean-up when a class instance is being collected by the garbage collector. In most cases, you can avoid writing a finalizer by using the [System.Runtime.InteropServices.SafeHandle](#) or derived classes to wrap any unmanaged handle.

Remarks

- Finalizers cannot be defined in structs. They are only used with classes.
- A class can only have one finalizer.
- Finalizers cannot be inherited or overloaded.
- Finalizers cannot be called. They are invoked automatically.
- A finalizer does not take modifiers or have parameters.

For example, the following is a declaration of a finalizer for the `Car` class.

```
class Car
{
    ~Car() // finalizer
    {
        // cleanup statements...
    }
}
```

A finalizer can also be implemented as an expression body definition, as the following example shows.

```
using System;

public class Destroyer
{
    public override string ToString() => GetType().Name;

    ~Destroyer() => Console.WriteLine($"The {ToString()} finalizer is executing.");
}
```

The finalizer implicitly calls [Finalize](#) on the base class of the object. Therefore, a call to a finalizer is implicitly translated to the following code:

```
protected override void Finalize()
{
    try
    {
        // Cleanup statements...
    }
    finally
    {
        base.Finalize();
    }
}
```

This design means that the `Finalize` method is called recursively for all instances in the inheritance chain, from the most-derived to the least-derived.

NOTE

Empty finalizers should not be used. When a class contains a finalizer, an entry is created in the `Finalize` queue. This queue is processed the garbage collector. When the GC processes the queue, it calls each finalizer. Unnecessary finalizers, including empty finalizers, finalizers that only call the base class finalizer, or finalizers that only call conditionally emitted methods cause a needless loss of performance.

The programmer has no control over when the finalizer is called; the garbage collector decides when to call it. The garbage collector checks for objects that are no longer being used by the application. If it considers an object eligible for finalization, it calls the finalizer (if any) and reclaims the memory used to store the object. It's possible to force garbage collection by calling `Collect`, but most of the time, this call should be avoided because it may create performance issues.

NOTE

Whether or not finalizers are run as part of application termination is specific to each [implementation of .NET](#). When an application terminates, .NET Framework makes every reasonable effort to call finalizers for objects that haven't yet been garbage collected, unless such cleanup has been suppressed (by a call to the library method `GC.SuppressFinalize`, for example). .NET 5 (including .NET Core) and later versions don't call finalizers as part of application termination. For more information, see GitHub issue [dotnet/csharpstandard #291](#).

If you need to perform cleanup reliably when an application exits, register a handler for the `System.AppDomain.ProcessExit` event. That handler would ensure `IDisposable.Dispose()` (or, `IAsyncDisposable.DisposeAsync()`) has been called for all objects that require cleanup before application exit. Because you can't call `Finalize` directly, and you can't guarantee the garbage collector calls all finalizers before exit, you must use `Dispose` or `DisposeAsync` to ensure resources are freed.

Using finalizers to release resources

In general, C# does not require as much memory management on the part of the developer as languages that don't target a runtime with garbage collection. This is because the .NET garbage collector implicitly manages the allocation and release of memory for your objects. However, when your application encapsulates unmanaged resources, such as windows, files, and network connections, you should use finalizers to free those resources. When the object is eligible for finalization, the garbage collector runs the `Finalize` method of the object.

Explicit release of resources

If your application is using an expensive external resource, we also recommend that you provide a way to explicitly release the resource before the garbage collector frees the object. To release the resource, implement a `Dispose` method from the `IDisposable` interface that performs the necessary cleanup for the object. This can considerably improve the performance of the application. Even with this explicit control over resources, the finalizer becomes a safeguard to clean up resources if the call to the `Dispose` method fails.

For more information about cleaning up resources, see the following articles:

- [Cleaning Up Unmanaged Resources](#)
- [Implementing a Dispose Method](#)
- [Implementing a DisposeAsync Method](#)
- [using Statement](#)

Example

The following example creates three classes that make a chain of inheritance. The class `First` is the base class, `Second` is derived from `First`, and `Third` is derived from `Second`. All three have finalizers. In `Main`, an instance of the most-derived class is created. The output from this code depends on which implementation of .NET the application targets:

- .NET Framework: The output shows that the finalizers for the three classes are called automatically when the application terminates, in order from the most-derived to the least-derived.
- .NET 5 (including .NET Core) or a later version: There's no output, because this implementation of .NET doesn't call finalizers when the application terminates.

```
class First
{
    ~First()
    {
        System.Diagnostics.Trace.WriteLine("First's finalizer is called.");
    }
}

class Second : First
{
    ~Second()
    {
        System.Diagnostics.Trace.WriteLine("Second's finalizer is called.");
    }
}

class Third : Second
{
    ~Third()
    {
        System.Diagnostics.Trace.WriteLine("Third's finalizer is called.");
    }
}

/*
Test with code like the following:
    Third t = new Third();
    t = null;

When objects are finalized, the output would be:
Third's finalizer is called.
Second's finalizer is called.
First's finalizer is called.
*/
```

Object and Collection Initializers (C# Programming Guide)

12/28/2021 • 9 minutes to read • [Edit Online](#)

C# lets you instantiate an object or collection and perform member assignments in a single statement.

Object initializers

Object initializers let you assign values to any accessible fields or properties of an object at creation time without having to invoke a constructor followed by lines of assignment statements. The object initializer syntax enables you to specify arguments for a constructor or omit the arguments (and parentheses syntax). The following example shows how to use an object initializer with a named type, `Cat` and how to invoke the parameterless constructor. Note the use of auto-implemented properties in the `Cat` class. For more information, see [Auto-Implemented Properties](#).

```
public class Cat
{
    // Auto-implemented properties.
    public int Age { get; set; }
    public string Name { get; set; }

    public Cat()
    {
    }

    public Cat(string name)
    {
        this.Name = name;
    }
}
```

```
Cat cat = new Cat { Age = 10, Name = "Fluffy" };
Cat sameCat = new Cat("Fluffy"){ Age = 10 };
```

The object initializers syntax allows you to create an instance, and after that it assigns the newly created object, with its assigned properties, to the variable in the assignment.

Starting with C# 6, object initializers can set indexers, in addition to assigning fields and properties. Consider this basic `Matrix` class:

```
public class Matrix
{
    private double[,] storage = new double[3, 3];

    public double this[int row, int column]
    {
        // The embedded array will throw out of range exceptions as appropriate.
        get { return storage[row, column]; }
        set { storage[row, column] = value; }
    }
}
```

You could initialize the identity matrix with the following code:

```
var identity = new Matrix
{
    [0, 0] = 1.0,
    [0, 1] = 0.0,
    [0, 2] = 0.0,

    [1, 0] = 0.0,
    [1, 1] = 1.0,
    [1, 2] = 0.0,

    [2, 0] = 0.0,
    [2, 1] = 0.0,
    [2, 2] = 1.0,
};
```

Any accessible indexer that contains an accessible setter can be used as one of the expressions in an object initializer, regardless of the number or types of arguments. The index arguments form the left side of the assignment, and the value is the right side of the expression. For example, these are all valid if `IndexersExample` has the appropriate indexers:

```
var thing = new IndexersExample {
    name = "object one",
    [1] = '1',
    [2] = '4',
    [3] = '9',
    Size = Math.PI,
    ['C',4] = "Middle C"
}
```

For the preceding code to compile, the `IndexersExample` type must have the following members:

```
public string name;
public double Size { set { ... }; }
public char this[int i] { set { ... }; }
public string this[char c, int i] { set { ... }; }
```

Object Initializers with anonymous types

Although object initializers can be used in any context, they are especially useful in LINQ query expressions. Query expressions make frequent use of [anonymous types](#), which can only be initialized by using an object initializer, as shown in the following declaration.

```
var pet = new { Age = 10, Name = "Fluffy" };
```

Anonymous types enable the `select` clause in a LINQ query expression to transform objects of the original sequence into objects whose value and shape may differ from the original. This is useful if you want to store only a part of the information from each object in a sequence. In the following example, assume that a product object (`p`) contains many fields and methods, and that you are only interested in creating a sequence of objects that contain the product name and the unit price.

```
var productInfos =
    from p in products
    select new { p.ProductName, p.UnitPrice };
```

When this query is executed, the `productInfos` variable will contain a sequence of objects that can be accessed in a `foreach` statement as shown in this example:

```
foreach(var p in productInfos){...}
```

Each object in the new anonymous type has two public properties that receive the same names as the properties or fields in the original object. You can also rename a field when you are creating an anonymous type; the following example renames the `UnitPrice` field to `Price`.

```
select new {p.ProductName, Price = p.UnitPrice};
```

Collection initializers

Collection initializers let you specify one or more element initializers when you initialize a collection type that implements [IEnumerable](#) and has `Add` with the appropriate signature as an instance method or an extension method. The element initializers can be a simple value, an expression, or an object initializer. By using a collection initializer, you do not have to specify multiple calls; the compiler adds the calls automatically.

The following example shows two simple collection initializers:

```
List<int> digits = new List<int> { 0, 1, 2, 3, 4, 5, 6, 7, 8, 9 };
List<int> digits2 = new List<int> { 0 + 1, 12 % 3, MakeInt() };
```

The following collection initializer uses object initializers to initialize objects of the `Cat` class defined in a previous example. Note that the individual object initializers are enclosed in braces and separated by commas.

```
List<Cat> cats = new List<Cat>
{
    new Cat{ Name = "Sylvester", Age=8 },
    new Cat{ Name = "Whiskers", Age=2 },
    new Cat{ Name = "Sasha", Age=14 }
};
```

You can specify `null` as an element in a collection initializer if the collection's `Add` method allows it.

```
List<Cat> moreCats = new List<Cat>
{
    new Cat{ Name = "Furrytail", Age=5 },
    new Cat{ Name = "Peaches", Age=4 },
    null
};
```

You can specify indexed elements if the collection supports read / write indexing.

```
var numbers = new Dictionary<int, string>
{
    [7] = "seven",
    [9] = "nine",
    [13] = "thirteen"
};
```

The preceding sample generates code that calls the `Item[TKey]` to set the values. Before C# 6, you could initialize dictionaries and other associative containers using the following syntax. Notice that instead of indexer syntax,

with parentheses and an assignment, it uses an object with multiple values:

```
var moreNumbers = new Dictionary<int, string>
{
    {19, "nineteen" },
    {23, "twenty-three" },
    {42, "forty-two" }
};
```

This initializer example calls [Add\(TKey, TValue\)](#) to add the three items into the dictionary. These two different ways to initialize associative collections have slightly different behavior because of the method calls the compiler generates. Both variants work with the `Dictionary` class. Other types may only support one or the other based on their public API.

Object Initializers with collection read-only property initialization

Some classes may have collection properties where the property is read-only, like the `Cats` property of `CatOwner` in the following case:

```
public class CatOwner
{
    public IList<Cat> Cats { get; } = new List<Cat>();
}
```

You will not be able to use collection initializer syntax discussed so far since the property cannot be assigned a new list:

```
CatOwner owner = new CatOwner
{
    Cats = new List<Cat>
    {
        new Cat{ Name = "Sylvester", Age=8 },
        new Cat{ Name = "Whiskers", Age=2 },
        new Cat{ Name = "Sasha", Age=14 }
    }
};
```

However, new entries can be added to `Cats` nonetheless using the initialization syntax by omitting the list creation (`new List<Cat>`), as shown next:

```
CatOwner owner = new CatOwner
{
    Cats =
    {
        new Cat{ Name = "Sylvester", Age=8 },
        new Cat{ Name = "Whiskers", Age=2 },
        new Cat{ Name = "Sasha", Age=14 }
    }
};
```

The set of entries to be added simply appear surrounded by braces. The above is identical to writing:

```
CatOwner owner = new CatOwner();
owner.Cats.Add(new Cat{ Name = "Sylvester", Age=8 });
owner.Cats.Add(new Cat{ Name = "Whiskers", Age=2 });
owner.Cats.Add(new Cat{ Name = "Sasha", Age=14 });
```

Examples

The following example combines the concepts of object and collection initializers.

```
public class InitializationSample
{
    public class Cat
    {
        // Auto-implemented properties.
        public int Age { get; set; }
        public string Name { get; set; }

        public Cat() { }

        public Cat(string name)
        {
            Name = name;
        }
    }

    public static void Main()
    {
        Cat cat = new Cat { Age = 10, Name = "Fluffy" };
        Cat sameCat = new Cat("Fluffy"){ Age = 10 };

        List<Cat> cats = new List<Cat>
        {
            new Cat { Name = "Sylvester", Age = 8 },
            new Cat { Name = "Whiskers", Age = 2 },
            new Cat { Name = "Sasha", Age = 14 }
        };

        List<Cat> moreCats = new List<Cat>
        {
            new Cat { Name = "Furrytail", Age = 5 },
            new Cat { Name = "Peaches", Age = 4 },
            null
        };

        // Display results.
        System.Console.WriteLine(cat.Name);

        foreach (Cat c in cats)
            System.Console.WriteLine(c.Name);

        foreach (Cat c in moreCats)
            if (c != null)
                System.Console.WriteLine(c.Name);
            else
                System.Console.WriteLine("List element has null value.");
    }
    // Output:
    //Fluffy
    //Sylvester
    //Whiskers
    //Sasha
    //Furrytail
    //Peaches
    //List element has null value.
}
```

The following example shows an object that implements [IEnumerable](#) and contains an `Add` method with multiple parameters. It uses a collection initializer with multiple elements per item in the list that correspond to the signature of the `Add` method.

```

public class FullExample
{
    class FormattedAddresses : IEnumerable<string>
    {
        private List<string> internalList = new List<string>();
        public IEnumerator<string> GetEnumerator() => internalList.GetEnumerator();

        System.Collections.IEnumerator System.Collections.IEnumerable.GetEnumerator() =>
internalList.GetEnumerator();

        public void Add(string firstname, string lastname,
            string street, string city,
            string state, string zipcode) => internalList.Add(
                $"{firstname} {lastname}
{street}
{city}, {state} {zipcode}"
            );
    }

    public static void Main()
    {
        FormattedAddresses addresses = new FormattedAddresses()
        {
            {"John", "Doe", "123 Street", "Topeka", "KS", "00000" },
            {"Jane", "Smith", "456 Street", "Topeka", "KS", "00000" }
        };

        Console.WriteLine("Address Entries:");

        foreach (string addressEntry in addresses)
        {
            Console.WriteLine("\r\n" + addressEntry);
        }
    }

    /*
    * Prints:

    Address Entries:

    John Doe
    123 Street
    Topeka, KS 00000

    Jane Smith
    456 Street
    Topeka, KS 00000
    */
}

```

`Add` methods can use the `params` keyword to take a variable number of arguments, as shown in the following example. This example also demonstrates the custom implementation of an indexer to initialize a collection using indexes.

```

public class DictionaryExample
{
    class RudimentaryMultiValuedDictionary<TKey, TValue> : IEnumerable<KeyValuePair<TKey, List<TValue>>>
    {
        private Dictionary<TKey, List<TValue>> internalDictionary = new Dictionary<TKey, List<TValue>>>();

        public IEnumerator<KeyValuePair<TKey, List<TValue>>> GetEnumerator() =>
internalDictionary.GetEnumerator();

        System.Collections.IEnumerator System.Collections.IEnumerable.GetEnumerator() =>
internalDictionary.GetEnumerator();
    }
}

```

```

public List<TValue> this[TKey key]
{
    get => internalDictionary[key];
    set => Add(key, value);
}

public void Add(TKey key, params TValue[] values) => Add(key, (IEnumerable<TValue>)values);

public void Add(TKey key, IEnumerable<TValue> values)
{
    if (!internalDictionary.TryGetValue(key, out List<TValue> storedValues))
        internalDictionary.Add(key, storedValues = new List<TValue>());

    storedValues.AddRange(values);
}
}

public static void Main()
{
    RudimentaryMultiValuedDictionary<string, string> rudimentaryMultiValuedDictionary1
        = new RudimentaryMultiValuedDictionary<string, string>()
        {
            {"Group1", "Bob", "John", "Mary" },
            {"Group2", "Eric", "Emily", "Debbie", "Jesse" }
        };

    RudimentaryMultiValuedDictionary<string, string> rudimentaryMultiValuedDictionary2
        = new RudimentaryMultiValuedDictionary<string, string>()
        {
            ["Group1"] = new List<string>() { "Bob", "John", "Mary" },
            ["Group2"] = new List<string>() { "Eric", "Emily", "Debbie", "Jesse" }
        };

    RudimentaryMultiValuedDictionary<string, string> rudimentaryMultiValuedDictionary3
        = new RudimentaryMultiValuedDictionary<string, string>()
        {
            {"Group1", new string []{ "Bob", "John", "Mary" } },
            {"Group2", new string []{ "Eric", "Emily", "Debbie", "Jesse" } }
        };

    Console.WriteLine("Using first multi-valued dictionary created with a collection initializer:");

    foreach (KeyValuePair<string, List<string>> group in rudimentaryMultiValuedDictionary1)
    {
        Console.WriteLine($"\"\\r\\nMembers of group {group.Key}: ");

        foreach (string member in group.Value)
        {
            Console.WriteLine(member);
        }
    }

    Console.WriteLine("\\r\\nUsing second multi-valued dictionary created with a collection initializer using indexing:");

    foreach (KeyValuePair<string, List<string>> group in rudimentaryMultiValuedDictionary2)
    {
        Console.WriteLine($"\"\\r\\nMembers of group {group.Key}: ");

        foreach (string member in group.Value)
        {
            Console.WriteLine(member);
        }
    }

    Console.WriteLine("\\r\\nUsing third multi-valued dictionary created with a collection initializer using indexing:");

    foreach (KeyValuePair<string, List<string>> group in rudimentaryMultiValuedDictionary3)
    {
        Console.WriteLine($"\"\\r\\nMembers of group {group.Key}: ");
    }
}

```

```

        foreach (string member in group.Value)
        {
            Console.WriteLine(member);
        }
    }
}

/*
 * Prints:

    Using first multi-valued dictionary created with a collection initializer:

    Members of group Group1:
    Bob
    John
    Mary

    Members of group Group2:
    Eric
    Emily
    Debbie
    Jesse

    Using second multi-valued dictionary created with a collection initializer using indexing:

    Members of group Group1:
    Bob
    John
    Mary

    Members of group Group2:
    Eric
    Emily
    Debbie
    Jesse

    Using third multi-valued dictionary created with a collection initializer using indexing:

    Members of group Group1:
    Bob
    John
    Mary

    Members of group Group2:
    Eric
    Emily
    Debbie
    Jesse
 */
}

```

How to initialize objects by using an object initializer (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

You can use object initializers to initialize type objects in a declarative manner without explicitly invoking a constructor for the type.

The following examples show how to use object initializers with named objects. The compiler processes object initializers by first accessing the parameterless instance constructor and then processing the member initializations. Therefore, if the parameterless constructor is declared as `private` in the class, object initializers that require public access will fail.

You must use an object initializer if you're defining an anonymous type. For more information, see [How to return subsets of element properties in a query](#).

Example

The following example shows how to initialize a new `StudentName` type by using object initializers. This example sets properties in the `StudentName` type:

```
public class HowToObjectInitializers
{
    public static void Main()
    {
        // Declare a StudentName by using the constructor that has two parameters.
        StudentName student1 = new StudentName("Craig", "Playstead");

        // Make the same declaration by using an object initializer and sending
        // arguments for the first and last names. The parameterless constructor is
        // invoked in processing this declaration, not the constructor that has
        // two parameters.
        StudentName student2 = new StudentName
        {
            FirstName = "Craig",
            LastName = "Playstead"
        };

        // Declare a StudentName by using an object initializer and sending
        // an argument for only the ID property. No corresponding constructor is
        // necessary. Only the parameterless constructor is used to process object
        // initializers.
        StudentName student3 = new StudentName
        {
            ID = 183
        };

        // Declare a StudentName by using an object initializer and sending
        // arguments for all three properties. No corresponding constructor is
        // defined in the class.
        StudentName student4 = new StudentName
        {
            FirstName = "Craig",
            LastName = "Playstead",
            ID = 116
        };

        Console.WriteLine(student1.ToString());
        Console.WriteLine(student2.ToString());
    }
}
```

```

        Console.WriteLine(student2.ToString());
        Console.WriteLine(student3.ToString());
        Console.WriteLine(student4.ToString());
    }
    // Output:
    // Craig 0
    // Craig 0
    // 183
    // Craig 116

    public class StudentName
    {
        // This constructor has no parameters. The parameterless constructor
        // is invoked in the processing of object initializers.
        // You can test this by changing the access modifier from public to
        // private. The declarations in Main that use object initializers will
        // fail.
        public StudentName() { }

        // The following constructor has parameters for two of the three
        // properties.
        public StudentName(string first, string last)
        {
            FirstName = first;
            LastName = last;
        }

        // Properties.
        public string FirstName { get; set; }
        public string LastName { get; set; }
        public int ID { get; set; }

        public override string ToString() => FirstName + " " + ID;
    }
}

```

Object initializers can be used to set indexers in an object. The following example defines a `BaseballTeam` class that uses an indexer to get and set players at different positions. The initializer can assign players, based on the abbreviation for the position, or the number used for each position baseball scorecards:

```

public class HowToIndexInitializer
{
    public class BaseballTeam
    {
        private string[] players = new string[9];
        private readonly List<string> positionAbbreviations = new List<string>
        {
            "P", "C", "1B", "2B", "3B", "SS", "LF", "CF", "RF"
        };

        public string this[int position]
        {
            // Baseball positions are 1 - 9.
            get { return players[position-1]; }
            set { players[position-1] = value; }
        }
        public string this[string position]
        {
            get { return players[positionAbbreviations.IndexOf(position)]; }
            set { players[positionAbbreviations.IndexOf(position)] = value; }
        }
    }

    public static void Main()
    {
        var team = new BaseballTeam
        {
            ["RF"] = "Mookie Betts",
            [4] = "Jose Altuve",
            ["CF"] = "Mike Trout"
        };

        Console.WriteLine(team["2B"]);
    }
}

```

How to initialize a dictionary with a collection initializer (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

A `Dictionary<TKey,TValue>` contains a collection of key/value pairs. Its `Add` method takes two parameters, one for the key and one for the value. One way to initialize a `Dictionary<TKey,TValue>`, or any collection whose `Add` method takes multiple parameters, is to enclose each set of parameters in braces as shown in the following example. Another option is to use an index initializer, also shown in the following example.

Example

In the following code example, a `Dictionary<TKey,TValue>` is initialized with instances of type `StudentName`. The first initialization uses the `Add` method with two arguments. The compiler generates a call to `Add` for each of the pairs of `int` keys and `StudentName` values. The second uses a public read / write indexer method of the `Dictionary` class:

```
public class HowToDictionaryInitializer
{
    class StudentName
    {
        public string FirstName { get; set; }
        public string LastName { get; set; }
        public int ID { get; set; }
    }

    public static void Main()
    {
        var students = new Dictionary<int, StudentName>()
        {
            { 111, new StudentName { FirstName="Sachin", LastName="Karnik", ID=211 } },
            { 112, new StudentName { FirstName="Dina", LastName="Salimzianova", ID=317 } },
            { 113, new StudentName { FirstName="Andy", LastName="Ruth", ID=198 } }
        };

        foreach(var index in Enumerable.Range(111, 3))
        {
            Console.WriteLine($"Student {index} is {students[index].FirstName} {students[index].LastName}");
        }
        Console.WriteLine();

        var students2 = new Dictionary<int, StudentName>()
        {
            [111] = new StudentName { FirstName="Sachin", LastName="Karnik", ID=211 },
            [112] = new StudentName { FirstName="Dina", LastName="Salimzianova", ID=317 } ,
            [113] = new StudentName { FirstName="Andy", LastName="Ruth", ID=198 }
        };

        foreach (var index in Enumerable.Range(111, 3))
        {
            Console.WriteLine($"Student {index} is {students2[index].FirstName} {students2[index].LastName}");
        }
    }
}
```

Note the two pairs of braces in each element of the collection in the first declaration. The innermost braces

enclose the object initializer for the `StudentName`, and the outermost braces enclose the initializer for the key/value pair that will be added to the `students` [Dictionary<TKey,TValue>](#). Finally, the whole collection initializer for the dictionary is enclosed in braces. In the second initialization, the left side of the assignment is the key and the right side is the value, using an object initializer for `StudentName`.

Nested Types (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

A type defined within a [class](#), [struct](#), or [interface](#) is called a nested type. For example

```
public class Container
{
    class Nested
    {
        Nested() { }
    }
}
```

Regardless of whether the outer type is a class, interface, or struct, nested types default to [private](#); they are accessible only from their containing type. In the previous example, the `Nested` class is inaccessible to external types.

You can also specify an [access modifier](#) to define the accessibility of a nested type, as follows:

- Nested types of a **class** can be [public](#), [protected](#), [internal](#), [protected internal](#), [private](#) or [private protected](#).

However, defining a `protected`, `protected internal` or `private protected` nested class inside a [sealed class](#) generates compiler warning [CS0628](#), "new protected member declared in sealed class."

Also be aware that making a nested type externally visible violates the code quality rule [CA1034](#) "Nested types should not be visible".

- Nested types of a **struct** can be [public](#), [internal](#), or [private](#).

The following example makes the `Nested` class public:

```
public class Container
{
    public class Nested
    {
        Nested() { }
    }
}
```

The nested, or inner, type can access the containing, or outer, type. To access the containing type, pass it as an argument to the constructor of the nested type. For example:

```
public class Container
{
    public class Nested
    {
        private Container parent;

        public Nested()
        {
        }
        public Nested(Container parent)
        {
            this.parent = parent;
        }
    }
}
```

A nested type has access to all of the members that are accessible to its containing type. It can access private and protected members of the containing type, including any inherited protected members.

In the previous declaration, the full name of class `Nested` is `Container.Nested`. This is the name used to create a new instance of the nested class, as follows:

```
Container.Nested nest = new Container.Nested();
```

Partial Classes and Methods (C# Programming Guide)

12/28/2021 • 6 minutes to read • [Edit Online](#)

It is possible to split the definition of a [class](#), a [struct](#), an [interface](#) or a method over two or more source files. Each source file contains a section of the type or method definition, and all parts are combined when the application is compiled.

Partial Classes

There are several situations when splitting a class definition is desirable:

- When working on large projects, spreading a class over separate files enables multiple programmers to work on it at the same time.
- When working with automatically generated source, code can be added to the class without having to recreate the source file. Visual Studio uses this approach when it creates Windows Forms, Web service wrapper code, and so on. You can create code that uses these classes without having to modify the file created by Visual Studio.
- When using [source generators](#) to generate additional functionality in a class.

To split a class definition, use the [partial](#) keyword modifier, as shown here:

```
public partial class Employee
{
    public void DoWork()
    {
    }
}

public partial class Employee
{
    public void GoToLunch()
    {
    }
}
```

The `partial` keyword indicates that other parts of the class, struct, or interface can be defined in the namespace. All the parts must use the `partial` keyword. All the parts must be available at compile time to form the final type. All the parts must have the same accessibility, such as `public`, `private`, and so on.

If any part is declared abstract, then the whole type is considered abstract. If any part is declared sealed, then the whole type is considered sealed. If any part declares a base type, then the whole type inherits that class.

All the parts that specify a base class must agree, but parts that omit a base class still inherit the base type. Parts can specify different base interfaces, and the final type implements all the interfaces listed by all the partial declarations. Any class, struct, or interface members declared in a partial definition are available to all the other parts. The final type is the combination of all the parts at compile time.

NOTE

The `partial` modifier is not available on delegate or enumeration declarations.

The following example shows that nested types can be partial, even if the type they are nested within is not partial itself.

```
class Container
{
    partial class Nested
    {
        void Test() { }
    }

    partial class Nested
    {
        void Test2() { }
    }
}
```

At compile time, attributes of partial-type definitions are merged. For example, consider the following declarations:

```
[SerializableAttribute]
partial class Moon { }

[ObsoleteAttribute]
partial class Moon { }
```

They are equivalent to the following declarations:

```
[SerializableAttribute]
[ObsoleteAttribute]
class Moon { }
```

The following are merged from all the partial-type definitions:

- XML comments
- interfaces
- generic-type parameter attributes
- class attributes
- members

For example, consider the following declarations:

```
partial class Earth : Planet, IRotate { }
partial class Earth : IRevolve { }
```

They are equivalent to the following declarations:

```
class Earth : Planet, IRotate, IRevolve { }
```

Restrictions

There are several rules to follow when you are working with partial class definitions:

- All partial-type definitions meant to be parts of the same type must be modified with `partial`. For example, the following class declarations generate an error:

```
public partial class A { }  
//public class A { } // Error, must also be marked partial
```

- The `partial` modifier can only appear immediately before the keywords `class`, `struct`, or `interface`.
- Nested partial types are allowed in partial-type definitions as illustrated in the following example:

```
partial class ClassWithNestedClass  
{  
    partial class NestedClass { }  
}  
  
partial class ClassWithNestedClass  
{  
    partial class NestedClass { }  
}
```

- All partial-type definitions meant to be parts of the same type must be defined in the same assembly and the same module (.exe or .dll file). Partial definitions cannot span multiple modules.
- The class name and generic-type parameters must match on all partial-type definitions. Generic types can be partial. Each partial declaration must use the same parameter names in the same order.
- The following keywords on a partial-type definition are optional, but if present on one partial-type definition, cannot conflict with the keywords specified on another partial definition for the same type:
 - `public`
 - `private`
 - `protected`
 - `internal`
 - `abstract`
 - `sealed`
 - base class
 - `new` modifier (nested parts)
 - generic constraints

For more information, see [Constraints on Type Parameters](#).

Examples

In the following example, the fields and the constructor of the class, `Coords`, are declared in one partial class definition, and the member, `PrintCoords`, is declared in another partial class definition.

```

public partial class Coords
{
    private int x;
    private int y;

    public Coords(int x, int y)
    {
        this.x = x;
        this.y = y;
    }
}

public partial class Coords
{
    public void PrintCoords()
    {
        Console.WriteLine("Coords: {0},{1}", x, y);
    }
}

class TestCoords
{
    static void Main()
    {
        Coords myCoords = new Coords(10, 15);
        myCoords.PrintCoords();

        // Keep the console window open in debug mode.
        Console.WriteLine("Press any key to exit.");
        Console.ReadKey();
    }
}
// Output: Coords: 10,15

```

The following example shows that you can also develop partial structs and interfaces.

```

partial interface ITest
{
    void Interface_Test();
}

partial interface ITest
{
    void Interface_Test2();
}

partial struct S1
{
    void Struct_Test() { }
}

partial struct S1
{
    void Struct_Test2() { }
}

```

Partial Methods

A partial class or struct may contain a partial method. One part of the class contains the signature of the method. An implementation can be defined in the same part or another part. If the implementation is not supplied, then the method and all calls to the method are removed at compile time. Implementation may be required depending on method signature. A partial method isn't required to have an implementation in the

following cases:

- It doesn't have any accessibility modifiers (including the default [private](#)).
- It returns [void](#).
- It doesn't have any [out](#) parameters.
- It doesn't have any of the following modifiers [virtual](#), [override](#), [sealed](#), [new](#), or [extern](#).

Any method that doesn't conform to all those restrictions (for example, `public virtual partial void method`), must provide an implementation. That implementation may be supplied by a *source generator*.

Partial methods enable the implementer of one part of a class to declare a method. The implementer of another part of the class can define that method. There are two scenarios where this is useful: templates that generate boilerplate code, and source generators.

- **Template code:** The template reserves a method name and signature so that generated code can call the method. These methods follow the restrictions that enable a developer to decide whether to implement the method. If the method is not implemented, then the compiler removes the method signature and all calls to the method. The calls to the method, including any results that would occur from evaluation of arguments in the calls, have no effect at run time. Therefore, any code in the partial class can freely use a partial method, even if the implementation is not supplied. No compile-time or run-time errors will result if the method is called but not implemented.
- **Source generators:** Source generators provide an implementation for methods. The human developer can add the method declaration (often with attributes read by the source generator). The developer can write code that calls these methods. The source generator runs during compilation and provides the implementation. In this scenario, the restrictions for partial methods that may not be implemented often aren't followed.

```
// Definition in file1.cs
partial void OnNameChanged();

// Implementation in file2.cs
partial void OnNameChanged()
{
    // method body
}
```

- Partial method declarations must begin with the contextual keyword [partial](#).
- Partial method signatures in both parts of the partial type must match.
- Partial methods can have [static](#) and [unsafe](#) modifiers.
- Partial methods can be generic. Constraints are put on the defining partial method declaration, and may optionally be repeated on the implementing one. Parameter and type parameter names do not have to be the same in the implementing declaration as in the defining one.
- You can make a [delegate](#) to a partial method that has been defined and implemented, but not to a partial method that has only been defined.

C# Language Specification

For more information, see [Partial types](#) in the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

How to return subsets of element properties in a query (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Use an anonymous type in a query expression when both of these conditions apply:

- You want to return only some of the properties of each source element.
- You do not have to store the query results outside the scope of the method in which the query is executed.

If you only want to return one property or field from each source element, then you can just use the dot operator in the `select` clause. For example, to return only the `ID` of each `student`, write the `select` clause as follows:

```
select student.ID;
```

Example

The following example shows how to use an anonymous type to return only a subset of the properties of each source element that matches the specified condition.

```
private static void QueryByScore()
{
    // Create the query. var is required because
    // the query produces a sequence of anonymous types.
    var queryHighScores =
        from student in students
        where student.ExamScores[0] > 95
        select new { student.FirstName, student.LastName };

    // Execute the query.
    foreach (var obj in queryHighScores)
    {
        // The anonymous type's properties were not named. Therefore
        // they have the same names as the Student properties.
        Console.WriteLine(obj.FirstName + ", " + obj.LastName);
    }
}

/* Output:
Adams, Terry
Fakhouri, Fadi
Garcia, Cesar
Omelchenko, Svetlana
Zabokritski, Eugene
*/
```

Note that the anonymous type uses the source element's names for its properties if no names are specified. To give new names to the properties in the anonymous type, write the `select` statement as follows:

```
select new { First = student.FirstName, Last = student.LastName };
```

If you try this in the previous example, then the `Console.WriteLine` statement must also change:

```
Console.WriteLine(student.First + " " + student.Last);
```

Compiling the Code

To run this code, copy and paste the class into a C# console application with a `using` directive for `System.Linq`.

Explicit Interface Implementation (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

If a [class](#) implements two interfaces that contain a member with the same signature, then implementing that member on the class will cause both interfaces to use that member as their implementation. In the following example, all the calls to `Paint` invoke the same method. This first sample defines the types:

```
public interface IControl
{
    void Paint();
}
public interface ISurface
{
    void Paint();
}
public class SampleClass : IControl, ISurface
{
    // Both ISurface.Paint and IControl.Paint call this method.
    public void Paint()
    {
        Console.WriteLine("Paint method in SampleClass");
    }
}
```

The following sample calls the methods:

```
SampleClass sample = new SampleClass();
IControl control = sample;
ISurface surface = sample;

// The following lines all call the same method.
sample.Paint();
control.Paint();
surface.Paint();

// Output:
// Paint method in SampleClass
// Paint method in SampleClass
// Paint method in SampleClass
```

But you might not want the same implementation to be called for both interfaces. To call a different implementation depending on which interface is in use, you can implement an interface member explicitly. An explicit interface implementation is a class member that is only called through the specified interface. Name the class member by prefixing it with the name of the interface and a period. For example:

```
public class SampleClass : IControl, ISurface
{
    void IControl.Paint()
    {
        System.Console.WriteLine("IControl.Paint");
    }
    void ISurface.Paint()
    {
        System.Console.WriteLine("ISurface.Paint");
    }
}
```

The class member `IControl.Paint` is only available through the `IControl` interface, and `ISurface.Paint` is only available through `ISurface`. Both method implementations are separate, and neither are available directly on the class. For example:

```
SampleClass sample = new SampleClass();
IControl control = sample;
ISurface surface = sample;

// The following lines all call the same method.
//sample.Paint(); // Compiler error.
control.Paint(); // Calls IControl.Paint on SampleClass.
surface.Paint(); // Calls ISurface.Paint on SampleClass.

// Output:
// IControl.Paint
// ISurface.Paint
```

Explicit implementation is also used to resolve cases where two interfaces each declare different members of the same name such as a property and a method. To implement both interfaces, a class has to use explicit implementation either for the property `P`, or the method `P`, or both, to avoid a compiler error. For example:

```
interface ILeft
{
    int P { get; }
}
interface IRight
{
    int P();
}

class Middle : ILeft, IRight
{
    public int P() { return 0; }
    int ILeft.P { get { return 0; } }
}
```

An explicit interface implementation doesn't have an access modifier since it isn't accessible as a member of the type it's defined in. Instead, it's only accessible when called through an instance of the interface. If you specify an access modifier for an explicit interface implementation, you get compiler error [CS0106](#). For more information, see [interface](#) (C# Reference).

Beginning with [C# 8.0](#), you can define an implementation for members declared in an interface. If a class inherits a method implementation from an interface, that method is only accessible through a reference of the interface type. The inherited member doesn't appear as part of the public interface. The following sample defines a default implementation for an interface method:

```
public interface IControl
{
    void Paint() => Console.WriteLine("Default Paint method");
}
public class SampleClass : IControl
{
    // Paint() is inherited from IControl.
}
```

The following sample invokes the default implementation:

```
var sample = new SampleClass();
//sample.Paint();// "Paint" isn't accessible.
var control = sample as IControl;
control.Paint();
```

Any class that implements the `IControl` interface can override the default `Paint` method, either as a public method, or as an explicit interface implementation.

How to explicitly implement interface members (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

This example declares an `interface`, `IDimensions`, and a class, `Box`, which explicitly implements the interface members `GetLength` and `GetWidth`. The members are accessed through the interface instance `dimensions`.

Example

```

interface IDimensions
{
    float GetLength();
    float GetWidth();
}

class Box : IDimensions
{
    float lengthInches;
    float widthInches;

    Box(float length, float width)
    {
        lengthInches = length;
        widthInches = width;
    }
    // Explicit interface member implementation:
    float IDimensions.GetLength()
    {
        return lengthInches;
    }
    // Explicit interface member implementation:
    float IDimensions.GetWidth()
    {
        return widthInches;
    }

    static void Main()
    {
        // Declare a class instance box1:
        Box box1 = new Box(30.0f, 20.0f);

        // Declare an interface instance dimensions:
        IDimensions dimensions = box1;

        // The following commented lines would produce compilation
        // errors because they try to access an explicitly implemented
        // interface member from a class instance:
        //System.Console.WriteLine("Length: {0}", box1.GetLength());
        //System.Console.WriteLine("Width: {0}", box1.GetWidth());

        // Print out the dimensions of the box by calling the methods
        // from an instance of the interface:
        System.Console.WriteLine("Length: {0}", dimensions.GetLength());
        System.Console.WriteLine("Width: {0}", dimensions.GetWidth());
    }
}
/* Output:
    Length: 30
    Width: 20
*/

```

Robust Programming

- Notice that the following lines, in the `Main` method, are commented out because they would produce compilation errors. An interface member that is explicitly implemented cannot be accessed from a [class](#) instance:

```

//System.Console.WriteLine("Length: {0}", box1.GetLength());
//System.Console.WriteLine("Width: {0}", box1.GetWidth());

```

- Notice also that the following lines, in the `Main` method, successfully print out the dimensions of the box because the methods are being called from an instance of the interface:

```
System.Console.WriteLine("Length: {0}", dimensions.GetLength());  
System.Console.WriteLine("Width: {0}", dimensions.GetWidth());
```

How to explicitly implement members of two interfaces (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Explicit [interface](#) implementation also allows the programmer to implement two interfaces that have the same member names and give each interface member a separate implementation. This example displays the dimensions of a box in both metric and English units. The Box [class](#) implements two interfaces `IEnglishDimensions` and `IMetricDimensions`, which represent the different measurement systems. Both interfaces have identical member names, `Length` and `Width`.

Example

```

// Declare the English units interface:
interface IEnglishDimensions
{
    float Length();
    float Width();
}

// Declare the metric units interface:
interface IMetricDimensions
{
    float Length();
    float Width();
}

// Declare the Box class that implements the two interfaces:
// IEnglishDimensions and IMetricDimensions:
class Box : IEnglishDimensions, IMetricDimensions
{
    float lengthInches;
    float widthInches;

    public Box(float lengthInches, float widthInches)
    {
        this.lengthInches = lengthInches;
        this.widthInches = widthInches;
    }

    // Explicitly implement the members of IEnglishDimensions:
    float IEnglishDimensions.Length() => lengthInches;

    float IEnglishDimensions.Width() => widthInches;

    // Explicitly implement the members of IMetricDimensions:
    float IMetricDimensions.Length() => lengthInches * 2.54f;

    float IMetricDimensions.Width() => widthInches * 2.54f;

    static void Main()
    {
        // Declare a class instance box1:
        Box box1 = new Box(30.0f, 20.0f);

        // Declare an instance of the English units interface:
        IEnglishDimensions eDimensions = box1;

        // Declare an instance of the metric units interface:
        IMetricDimensions mDimensions = box1;

        // Print dimensions in English units:
        System.Console.WriteLine("Length(in): {0}", eDimensions.Length());
        System.Console.WriteLine("Width (in): {0}", eDimensions.Width());

        // Print dimensions in metric units:
        System.Console.WriteLine("Length(cm): {0}", mDimensions.Length());
        System.Console.WriteLine("Width (cm): {0}", mDimensions.Width());
    }
}

/* Output:
    Length(in): 30
    Width (in): 20
    Length(cm): 76.2
    Width (cm): 50.8
*/

```

If you want to make the default measurements in English units, implement the methods `Length` and `Width` normally, and explicitly implement the `Length` and `Width` methods from the `IMetricDimensions` interface:

```
// Normal implementation:
public float Length() => lengthInches;
public float Width() => widthInches;

// Explicit implementation:
float IMetricDimensions.Length() => lengthInches * 2.54f;
float IMetricDimensions.Width() => widthInches * 2.54f;
```

In this case, you can access the English units from the class instance and access the metric units from the interface instance:

```
public static void Test()
{
    Box box1 = new Box(30.0f, 20.0f);
    IMetricDimensions mDimensions = box1;

    System.Console.WriteLine("Length(in): {0}", box1.Length());
    System.Console.WriteLine("Width (in): {0}", box1.Width());
    System.Console.WriteLine("Length(cm): {0}", mDimensions.Length());
    System.Console.WriteLine("Width (cm): {0}", mDimensions.Width());
}
```

Delegates (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

A [delegate](#) is a type that represents references to methods with a particular parameter list and return type. When you instantiate a delegate, you can associate its instance with any method with a compatible signature and return type. You can invoke (or call) the method through the delegate instance.

Delegates are used to pass methods as arguments to other methods. Event handlers are nothing more than methods that are invoked through delegates. You create a custom method, and a class such as a windows control can call your method when a certain event occurs. The following example shows a delegate declaration:

```
public delegate int PerformCalculation(int x, int y);
```

Any method from any accessible class or struct that matches the delegate type can be assigned to the delegate. The method can be either static or an instance method. This flexibility means you can programmatically change method calls, or plug new code into existing classes.

NOTE

In the context of method overloading, the signature of a method does not include the return value. But in the context of delegates, the signature does include the return value. In other words, a method must have the same return type as the delegate.

This ability to refer to a method as a parameter makes delegates ideal for defining callback methods. You can write a method that compares two objects in your application. That method can be used in a delegate for a sort algorithm. Because the comparison code is separate from the library, the sort method can be more general.

[Function pointers](#) were added to C# 9 for similar scenarios, where you need more control over the calling convention. The code associated with a delegate is invoked using a virtual method added to a delegate type. Using function pointers, you can specify different conventions.

Delegates Overview

Delegates have the following properties:

- Delegates are similar to C++ function pointers, but delegates are fully object-oriented, and unlike C++ pointers to member functions, delegates encapsulate both an object instance and a method.
- Delegates allow methods to be passed as parameters.
- Delegates can be used to define callback methods.
- Delegates can be chained together; for example, multiple methods can be called on a single event.
- Methods don't have to match the delegate type exactly. For more information, see [Using Variance in Delegates](#).
- Lambda expressions are a more concise way of writing inline code blocks. Lambda expressions (in certain contexts) are compiled to delegate types. For more information about lambda expressions, see [Lambda expressions](#).

Using Delegates (C# Programming Guide)

12/28/2021 • 5 minutes to read • [Edit Online](#)

A [delegate](#) is a type that safely encapsulates a method, similar to a function pointer in C and C++. Unlike C function pointers, delegates are object-oriented, type safe, and secure. The type of a delegate is defined by the name of the delegate. The following example declares a delegate named `Del` that can encapsulate a method that takes a [string](#) as an argument and returns [void](#):

```
public delegate void Del(string message);
```

A delegate object is normally constructed by providing the name of the method the delegate will wrap, or with a [lambda expression](#). Once a delegate is instantiated, a method call made to the delegate will be passed by the delegate to that method. The parameters passed to the delegate by the caller are passed to the method, and the return value, if any, from the method is returned to the caller by the delegate. This is known as invoking the delegate. An instantiated delegate can be invoked as if it were the wrapped method itself. For example:

```
// Create a method for a delegate.
public static void DelegateMethod(string message)
{
    Console.WriteLine(message);
}
```

```
// Instantiate the delegate.
Del handler = DelegateMethod;

// Call the delegate.
handler("Hello World");
```

Delegate types are derived from the [Delegate](#) class in .NET. Delegate types are [sealed](#)—they cannot be derived from—and it is not possible to derive custom classes from [Delegate](#). Because the instantiated delegate is an object, it can be passed as a parameter, or assigned to a property. This allows a method to accept a delegate as a parameter, and call the delegate at some later time. This is known as an asynchronous callback, and is a common method of notifying a caller when a long process has completed. When a delegate is used in this fashion, the code using the delegate does not need any knowledge of the implementation of the method being used. The functionality is similar to the encapsulation interfaces provide.

Another common use of callbacks is defining a custom comparison method and passing that delegate to a sort method. It allows the caller's code to become part of the sort algorithm. The following example method uses the `Del` type as a parameter:

```
public static void MethodWithCallback(int param1, int param2, Del callback)
{
    callback("The number is: " + (param1 + param2).ToString());
}
```

You can then pass the delegate created above to that method:

```
MethodWithCallback(1, 2, handler);
```

and receive the following output to the console:

```
The number is: 3
```

Using the delegate as an abstraction, `MethodWithCallback` does not need to call the console directly—it does not have to be designed with a console in mind. What `MethodWithCallback` does is simply prepare a string and pass the string to another method. This is especially powerful since a delegated method can use any number of parameters.

When a delegate is constructed to wrap an instance method, the delegate references both the instance and the method. A delegate has no knowledge of the instance type aside from the method it wraps, so a delegate can refer to any type of object as long as there is a method on that object that matches the delegate signature. When a delegate is constructed to wrap a static method, it only references the method. Consider the following declarations:

```
public class MethodClass
{
    public void Method1(string message) { }
    public void Method2(string message) { }
}
```

Along with the static `DelegateMethod` shown previously, we now have three methods that can be wrapped by a `Del` instance.

A delegate can call more than one method when invoked. This is referred to as multicasting. To add an extra method to the delegate's list of methods—the invocation list—simply requires adding two delegates using the addition or addition assignment operators ('+' or '+='). For example:

```
var obj = new MethodClass();
Del d1 = obj.Method1;
Del d2 = obj.Method2;
Del d3 = DelegateMethod;

//Both types of assignment are valid.
Del allMethodsDelegate = d1 + d2;
allMethodsDelegate += d3;
```

At this point `allMethodsDelegate` contains three methods in its invocation list—`Method1`, `Method2`, and `DelegateMethod`. The original three delegates, `d1`, `d2`, and `d3`, remain unchanged. When `allMethodsDelegate` is invoked, all three methods are called in order. If the delegate uses reference parameters, the reference is passed sequentially to each of the three methods in turn, and any changes by one method are visible to the next method. When any of the methods throws an exception that is not caught within the method, that exception is passed to the caller of the delegate and no subsequent methods in the invocation list are called. If the delegate has a return value and/or out parameters, it returns the return value and parameters of the last method invoked. To remove a method from the invocation list, use the [subtraction or subtraction assignment operators](#) (`-` or `-=`). For example:

```
//remove Method1
allMethodsDelegate -= d1;

// copy AllMethodsDelegate while removing d2
Del oneMethodDelegate = allMethodsDelegate - d2;
```

Because delegate types are derived from `System.Delegate`, the methods and properties defined by that class can

be called on the delegate. For example, to find the number of methods in a delegate's invocation list, you may write:

```
int invocationCount = d1.GetInvocationList().GetLength(0);
```

Delegates with more than one method in their invocation list derive from [MulticastDelegate](#), which is a subclass of `System.Delegate`. The above code works in either case because both classes support `GetInvocationList`.

Multicast delegates are used extensively in event handling. Event source objects send event notifications to recipient objects that have registered to receive that event. To register for an event, the recipient creates a method designed to handle the event, then creates a delegate for that method and passes the delegate to the event source. The source calls the delegate when the event occurs. The delegate then calls the event handling method on the recipient, delivering the event data. The delegate type for a given event is defined by the event source. For more, see [Events](#).

Comparing delegates of two different types assigned at compile-time will result in a compilation error. If the delegate instances are statically of the type `System.Delegate`, then the comparison is allowed, but will return false at run time. For example:

```
delegate void Delegate1();
delegate void Delegate2();

static void method(Delegate1 d, Delegate2 e, System.Delegate f)
{
    // Compile-time error.
    //Console.WriteLine(d == e);

    // OK at compile-time. False if the run-time type of f
    // is not the same as that of d.
    Console.WriteLine(d == f);
}
```

Delegates with Named vs. Anonymous Methods (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

A [delegate](#) can be associated with a named method. When you instantiate a delegate by using a named method, the method is passed as a parameter, for example:

```
// Declare a delegate.
delegate void Del(int x);

// Define a named method.
void DoWork(int k) { /* ... */ }

// Instantiate the delegate using the method as a parameter.
Del d = obj.DoWork;
```

This is called using a named method. Delegates constructed with a named method can encapsulate either a [static](#) method or an instance method. Named methods are the only way to instantiate a delegate in earlier versions of C#. However, in a situation where creating a new method is unwanted overhead, C# enables you to instantiate a delegate and immediately specify a code block that the delegate will process when it is called. The block can contain either a [lambda expression](#) or an [anonymous method](#).

The method that you pass as a delegate parameter must have the same signature as the delegate declaration. A delegate instance may encapsulate either static or instance method.

NOTE

Although the delegate can use an [out](#) parameter, we do not recommend its use with multicast event delegates because you cannot know which delegate will be called.

Beginning with C# 10, method groups with a single overload have a *natural type*. This means the compiler can infer the return type and parameter types for the delegate type:

```
var read = Console.Read; // Just one overload; Func<int> inferred
var write = Console.Write; // ERROR: Multiple overloads, can't choose
```

Examples

The following is a simple example of declaring and using a delegate. Notice that both the delegate, `Del`, and the associated method, `MultiplyNumbers`, have the same signature

```

// Declare a delegate
delegate void Del(int i, double j);

class MathClass
{
    static void Main()
    {
        MathClass m = new MathClass();

        // Delegate instantiation using "MultiplyNumbers"
        Del d = m.MultiplyNumbers;

        // Invoke the delegate object.
        Console.WriteLine("Invoking the delegate using 'MultiplyNumbers':");
        for (int i = 1; i <= 5; i++)
        {
            d(i, 2);
        }

        // Keep the console window open in debug mode.
        Console.WriteLine("Press any key to exit.");
        Console.ReadKey();
    }

    // Declare the associated method.
    void MultiplyNumbers(int m, double n)
    {
        Console.Write(m * n + " ");
    }
}
/* Output:
    Invoking the delegate using 'MultiplyNumbers':
    2 4 6 8 10
*/

```

In the following example, one delegate is mapped to both static and instance methods and returns specific information from each.

```

// Declare a delegate
delegate void Del();

class SampleClass
{
    public void InstanceMethod()
    {
        Console.WriteLine("A message from the instance method.");
    }

    static public void StaticMethod()
    {
        Console.WriteLine("A message from the static method.");
    }
}

class TestSampleClass
{
    static void Main()
    {
        var sc = new SampleClass();

        // Map the delegate to the instance method:
        Del d = sc.InstanceMethod;
        d();

        // Map to the static method:
        d = SampleClass.StaticMethod;
        d();
    }
}
/* Output:
    A message from the instance method.
    A message from the static method.
*/

```

How to combine delegates (Multicast Delegates) (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

This example demonstrates how to create multicast delegates. A useful property of `delegate` objects is that multiple objects can be assigned to one delegate instance by using the `+` operator. The multicast delegate contains a list of the assigned delegates. When the multicast delegate is called, it invokes the delegates in the list, in order. Only delegates of the same type can be combined.

The `-` operator can be used to remove a component delegate from a multicast delegate.

Example

```

using System;

// Define a custom delegate that has a string parameter and returns void.
delegate void CustomDel(string s);

class TestClass
{
    // Define two methods that have the same signature as CustomDel.
    static void Hello(string s)
    {
        Console.WriteLine($" Hello, {s}!");
    }

    static void Goodbye(string s)
    {
        Console.WriteLine($" Goodbye, {s}!");
    }

    static void Main()
    {
        // Declare instances of the custom delegate.
        CustomDel hiDel, byeDel, multiDel, multiMinusHiDel;

        // In this example, you can omit the custom delegate if you
        // want to and use Action<string> instead.
        //Action<string> hiDel, byeDel, multiDel, multiMinusHiDel;

        // Create the delegate object hiDel that references the
        // method Hello.
        hiDel = Hello;

        // Create the delegate object byeDel that references the
        // method Goodbye.
        byeDel = Goodbye;

        // The two delegates, hiDel and byeDel, are combined to
        // form multiDel.
        multiDel = hiDel + byeDel;

        // Remove hiDel from the multicast delegate, leaving byeDel,
        // which calls only the method Goodbye.
        multiMinusHiDel = multiDel - hiDel;

        Console.WriteLine("Invoking delegate hiDel:");
        hiDel("A");
        Console.WriteLine("Invoking delegate byeDel:");
        byeDel("B");
        Console.WriteLine("Invoking delegate multiDel:");
        multiDel("C");
        Console.WriteLine("Invoking delegate multiMinusHiDel:");
        multiMinusHiDel("D");
    }
}

/* Output:
Invoking delegate hiDel:
Hello, A!
Invoking delegate byeDel:
Goodbye, B!
Invoking delegate multiDel:
Hello, C!
Goodbye, C!
Invoking delegate multiMinusHiDel:
Goodbye, D!
*/

How to declare, instantiate, and use a Delegate (C# Programming Guide)

12/28/2021 • 4 minutes to read • [Edit Online](#)

In C# 1.0 and later, delegates can be declared as shown in the following example.

```
// Declare a delegate.
delegate void Del(string str);

// Declare a method with the same signature as the delegate.
static void Notify(string name)
{
    Console.WriteLine($"Notification received for: {name}");
}
```

```
// Create an instance of the delegate.
Del del1 = new Del(Notify);
```

C# 2.0 provides a simpler way to write the previous declaration, as shown in the following example.

```
// C# 2.0 provides a simpler way to declare an instance of Del.
Del del2 = Notify;
```

In C# 2.0 and later, it is also possible to use an anonymous method to declare and initialize a [delegate](#), as shown in the following example.

```
// Instantiate Del by using an anonymous method.
Del del3 = delegate(string name)
{ Console.WriteLine($"Notification received for: {name}"); };
```

In C# 3.0 and later, delegates can also be declared and instantiated by using a lambda expression, as shown in the following example.

```
// Instantiate Del by using a lambda expression.
Del del4 = name => { Console.WriteLine($"Notification received for: {name}"); };
```

For more information, see [Lambda Expressions](#).

The following example illustrates declaring, instantiating, and using a delegate. The `BookDB` class encapsulates a bookstore database that maintains a database of books. It exposes a method, `ProcessPaperbackBooks`, which finds all paperback books in the database and calls a delegate for each one. The `delegate` type that is used is named `ProcessBookCallback`. The `Test` class uses this class to print the titles and average price of the paperback books.

The use of delegates promotes good separation of functionality between the bookstore database and the client code. The client code has no knowledge of how the books are stored or how the bookstore code finds paperback books. The bookstore code has no knowledge of what processing is performed on the paperback books after it finds them.

Example

```
// A set of classes for handling a bookstore:
namespace Bookstore
{
    using System.Collections;

    // Describes a book in the book list:
    public struct Book
    {
        public string Title;           // Title of the book.
        public string Author;          // Author of the book.
        public decimal Price;          // Price of the book.
        public bool Paperback;          // Is it paperback?

        public Book(string title, string author, decimal price, bool paperBack)
        {
            Title = title;
            Author = author;
            Price = price;
            Paperback = paperBack;
        }
    }

    // Declare a delegate type for processing a book:
    public delegate void ProcessBookCallback(Book book);

    // Maintains a book database.
    public class BookDB
    {
        // List of all books in the database:
        ArrayList list = new ArrayList();

        // Add a book to the database:
        public void AddBook(string title, string author, decimal price, bool paperBack)
        {
            list.Add(new Book(title, author, price, paperBack));
        }

        // Call a passed-in delegate on each paperback book to process it:
        public void ProcessPaperbackBooks(ProcessBookCallback processBook)
        {
            foreach (Book b in list)
            {
                if (b.Paperback)
                {
                    // Calling the delegate:
                    processBook(b);
                }
            }
        }
    }
}

// Using the Bookstore classes:
namespace BookTestClient
{
    using Bookstore;

    // Class to total and average prices of books:
    class PriceTallier
    {
        int countBooks = 0;
        decimal priceBooks = 0.0m;

        internal void AddBookToTotal(Book book)
        {
            countBooks += 1;
            priceBooks += book.Price;
        }
    }
}
```

```

    }

    internal decimal AveragePrice()
    {
        return priceBooks / countBooks;
    }
}

// Class to test the book database:
class Test
{
    // Print the title of the book.
    static void PrintTitle(Book b)
    {
        Console.WriteLine($"    {b.Title}");
    }

    // Execution starts here.
    static void Main()
    {
        BookDB bookDB = new BookDB();

        // Initialize the database with some books:
        AddBooks(bookDB);

        // Print all the titles of paperbacks:
        Console.WriteLine("Paperback Book Titles:");

        // Create a new delegate object associated with the static
        // method Test.PrintTitle:
        bookDB.ProcessPaperbackBooks(PrintTitle);

        // Get the average price of a paperback by using
        // a PriceTallier object:
        PriceTallier tallier = new PriceTallier();

        // Create a new delegate object associated with the nonstatic
        // method AddBookToTotal on the object tallier:
        bookDB.ProcessPaperbackBooks(tallier.AddBookToTotal);

        Console.WriteLine("Average Paperback Book Price: ${0:0.##}",
            tallier.AveragePrice());
    }

    // Initialize the book database with some test books:
    static void AddBooks(BookDB bookDB)
    {
        bookDB.AddBook("The C Programming Language", "Brian W. Kernighan and Dennis M. Ritchie", 19.95m,
true);
        bookDB.AddBook("The Unicode Standard 2.0", "The Unicode Consortium", 39.95m, true);
        bookDB.AddBook("The MS-DOS Encyclopedia", "Ray Duncan", 129.95m, false);
        bookDB.AddBook("Dogbert's Clues for the Clueless", "Scott Adams", 12.00m, true);
    }
}

/* Output:
Paperback Book Titles:
    The C Programming Language
    The Unicode Standard 2.0
    Dogbert's Clues for the Clueless
Average Paperback Book Price: $23.97
*/

```

Robust Programming

- Declaring a delegate.

The following statement declares a new delegate type.

```
public delegate void ProcessBookCallback(Book book);
```

Each delegate type describes the number and types of the arguments, and the type of the return value of methods that it can encapsulate. Whenever a new set of argument types or return value type is needed, a new delegate type must be declared.

- Instantiating a delegate.

After a delegate type has been declared, a delegate object must be created and associated with a particular method. In the previous example, you do this by passing the `PrintTitle` method to the `ProcessPaperbackBooks` method as in the following example:

```
bookDB.ProcessPaperbackBooks(PrintTitle);
```

This creates a new delegate object associated with the [static](#) method `Test.PrintTitle`. Similarly, the non-static method `AddBookToTotal` on the object `totaller` is passed as in the following example:

```
bookDB.ProcessPaperbackBooks(totaller.AddBookToTotal);
```

In both cases a new delegate object is passed to the `ProcessPaperbackBooks` method.

After a delegate is created, the method it is associated with never changes; delegate objects are immutable.

- Calling a delegate.

After a delegate object is created, the delegate object is typically passed to other code that will call the delegate. A delegate object is called by using the name of the delegate object, followed by the parenthesized arguments to be passed to the delegate. Following is an example of a delegate call:

```
processBook(b);
```

A delegate can be either called synchronously, as in this example, or asynchronously by using `BeginInvoke` and `EndInvoke` methods.

Arrays (C# Programming Guide)

12/28/2021 • 3 minutes to read • [Edit Online](#)

You can store multiple variables of the same type in an array data structure. You declare an array by specifying the type of its elements. If you want the array to store elements of any type, you can specify `object` as its type. In the unified type system of C#, all types, predefined and user-defined, reference types and value types, inherit directly or indirectly from `Object`.

```
type[] arrayName;
```

Example

The following example creates single-dimensional, multidimensional, and jagged arrays:

```
class TestArraysClass
{
    static void Main()
    {
        // Declare a single-dimensional array of 5 integers.
        int[] array1 = new int[5];

        // Declare and set array element values.
        int[] array2 = new int[] { 1, 3, 5, 7, 9 };

        // Alternative syntax.
        int[] array3 = { 1, 2, 3, 4, 5, 6 };

        // Declare a two dimensional array.
        int[,] multiDimensionalArray1 = new int[2, 3];

        // Declare and set array element values.
        int[,] multiDimensionalArray2 = { { 1, 2, 3 }, { 4, 5, 6 } };

        // Declare a jagged array.
        int[][] jaggedArray = new int[6][];

        // Set the values of the first array in the jagged array structure.
        jaggedArray[0] = new int[4] { 1, 2, 3, 4 };
    }
}
```

Array overview

An array has the following properties:

- An array can be [single-dimensional](#), [multidimensional](#) or [jagged](#).
- The number of dimensions and the length of each dimension are established when the array instance is created. These values can't be changed during the lifetime of the instance.
- The default values of numeric array elements are set to zero, and reference elements are set to `null`.
- A jagged array is an array of arrays, and therefore its elements are reference types and are initialized to `null`.
- Arrays are zero indexed: an array with `n` elements is indexed from `0` to `n-1`.
- Array elements can be of any type, including an array type.

- Array types are [reference types](#) derived from the abstract base type [Array](#). All arrays implement [IList](#), and [IEnumerable](#). You can use the [foreach](#) statement to iterate through an array. Single-dimensional arrays also implement [IList<T>](#) and [IEnumerable<T>](#).

Default value behaviour

- For value types, the array elements are initialized with the [default value](#), the 0-bit pattern; the elements will have the value `0`.
- All the reference types (including the [non-nullable](#)), have the values `null`.
- For nullable value types, `HasValue` is set to `false` and the elements would be set to `null`.

Arrays as Objects

In C#, arrays are actually objects, and not just addressable regions of contiguous memory as in C and C++.

[Array](#) is the abstract base type of all array types. You can use the properties and other class members that [Array](#) has. An example of this is using the [Length](#) property to get the length of an array. The following code assigns the length of the `numbers` array, which is `5`, to a variable called `lengthOfNumbers`:

```
int[] numbers = { 1, 2, 3, 4, 5 };
int lengthOfNumbers = numbers.Length;
```

The [Array](#) class provides many other useful methods and properties for sorting, searching, and copying arrays. The following example uses the [Rank](#) property to display the number of dimensions of an array.

```
class TestArraysClass
{
    static void Main()
    {
        // Declare and initialize an array.
        int[,] theArray = new int[5, 10];
        System.Console.WriteLine("The array has {0} dimensions.", theArray.Rank);
    }
}
// Output: The array has 2 dimensions.
```

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

Single-Dimensional Arrays (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

You create a single-dimensional array using the `new` operator specifying the array element type and the number of elements. The following example declares an array of five integers:

```
int[] array = new int[5];
```

This array contains the elements from `array[0]` to `array[4]`. The elements of the array are initialized to the **default value** of the element type, `0` for integers.

Arrays can store any element type you specify, such as the following example that declares an array of strings:

```
string[] stringArray = new string[6];
```

Array Initialization

You can initialize the elements of an array when you declare the array. The length specifier isn't needed because it's inferred by the number of elements in the initialization list. For example:

```
int[] array1 = new int[] { 1, 3, 5, 7, 9 };
```

The following code shows a declaration of a string array where each array element is initialized by a name of a day:

```
string[] weekdays = new string[] { "Sun", "Mon", "Tue", "Wed", "Thu", "Fri", "Sat" };
```

You can avoid the `new` expression and the array type when you initialize an array upon declaration, as shown in the following code. This is called an **implicitly typed array**:

```
int[] array2 = { 1, 3, 5, 7, 9 };  
string[] weekdays2 = { "Sun", "Mon", "Tue", "Wed", "Thu", "Fri", "Sat" };
```

You can declare an array variable without creating it, but you must use the `new` operator when you assign a new array to this variable. For example:

```
int[] array3;  
array3 = new int[] { 1, 3, 5, 7, 9 }; // OK  
//array3 = {1, 3, 5, 7, 9}; // Error
```

Value Type and Reference Type Arrays

Consider the following array declaration:

```
SomeType[] array4 = new SomeType[10];
```

The result of this statement depends on whether `SomeType` is a value type or a reference type. If it's a value type, the statement creates an array of 10 elements, each of which has the type `SomeType`. If `SomeType` is a reference type, the statement creates an array of 10 elements, each of which is initialized to a null reference. In both instances, the elements are initialized to the default value for the element type. For more information about value types and reference types, see [Value types](#) and [Reference types](#).

Retrieving data from Array

You can retrieve the data of an array by using an index. For example:

```
string[] weekDays2 = { "Sun", "Mon", "Tue", "Wed", "Thu", "Fri", "Sat" };

Console.WriteLine(weekDays2[0]);
Console.WriteLine(weekDays2[1]);
Console.WriteLine(weekDays2[2]);
Console.WriteLine(weekDays2[3]);
Console.WriteLine(weekDays2[4]);
Console.WriteLine(weekDays2[5]);
Console.WriteLine(weekDays2[6]);

/*Output:
Sun
Mon
Tue
Wed
Thu
Fri
Sat
*/
```

- [Array](#)
- [Arrays](#)
- [Multidimensional Arrays](#)
- [Jagged Arrays](#)

Multidimensional Arrays (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Arrays can have more than one dimension. For example, the following declaration creates a two-dimensional array of four rows and two columns.

```
int[,] array = new int[4, 2];
```

The following declaration creates an array of three dimensions, 4, 2, and 3.

```
int[,,] array1 = new int[4, 2, 3];
```

Array Initialization

You can initialize the array upon declaration, as is shown in the following example.

```
// Two-dimensional array.
int[,] array2D = new int[,] { { 1, 2 }, { 3, 4 }, { 5, 6 }, { 7, 8 } };
// The same array with dimensions specified.
int[,] array2Da = new int[4, 2] { { 1, 2 }, { 3, 4 }, { 5, 6 }, { 7, 8 } };
// A similar array with string elements.
string[,] array2Db = new string[3, 2] { { "one", "two" }, { "three", "four" },
                                         { "five", "six" } };

// Three-dimensional array.
int[,,] array3D = new int[,,] { { { 1, 2, 3 }, { 4, 5, 6 } },
                                { { 7, 8, 9 }, { 10, 11, 12 } } };
// The same array with dimensions specified.
int[,,] array3Da = new int[2, 2, 3] { { { 1, 2, 3 }, { 4, 5, 6 } },
                                       { { 7, 8, 9 }, { 10, 11, 12 } } };

// Accessing array elements.
System.Console.WriteLine(array2D[0, 0]);
System.Console.WriteLine(array2D[0, 1]);
System.Console.WriteLine(array2D[1, 0]);
System.Console.WriteLine(array2D[1, 1]);
System.Console.WriteLine(array2D[3, 0]);
System.Console.WriteLine(array2Db[1, 0]);
System.Console.WriteLine(array3Da[1, 0, 1]);
System.Console.WriteLine(array3D[1, 1, 2]);

// Getting the total count of elements or the length of a given dimension.
var allLength = array3D.Length;
var total = 1;
for (int i = 0; i < array3D.Rank; i++)
{
    total *= array3D.GetLength(i);
}
System.Console.WriteLine("{0} equals {1}", allLength, total);

// Output:
// 1
// 2
// 3
// 4
// 7
// three
// 8
// 12
// 12 equals 12
```

You can also initialize the array without specifying the rank.

```
int[,] array4 = { { 1, 2 }, { 3, 4 }, { 5, 6 }, { 7, 8 } };
```

If you choose to declare an array variable without initialization, you must use the `new` operator to assign an array to the variable. The use of `new` is shown in the following example.

```
int[,] array5;
array5 = new int[,] { { 1, 2 }, { 3, 4 }, { 5, 6 }, { 7, 8 } }; // OK
//array5 = { {1,2}, {3,4}, {5,6}, {7,8} }; // Error
```

The following example assigns a value to a particular array element.

```
array5[2, 1] = 25;
```

Similarly, the following example gets the value of a particular array element and assigns it to variable

```
elementValue .
```

```
int elementValue = array5[2, 1];
```

The following code example initializes the array elements to default values (except for jagged arrays).

```
int[,] array6 = new int[10, 10];
```

Jagged Arrays (C# Programming Guide)

12/28/2021 • 3 minutes to read • [Edit Online](#)

A jagged array is an array whose elements are arrays, possibly of different sizes. A jagged array is sometimes called an "array of arrays." The following examples show how to declare, initialize, and access jagged arrays.

The following is a declaration of a single-dimensional array that has three elements, each of which is a single-dimensional array of integers:

```
int[][] jaggedArray = new int[3][];
```

Before you can use `jaggedArray`, its elements must be initialized. You can initialize the elements like this:

```
jaggedArray[0] = new int[5];
jaggedArray[1] = new int[4];
jaggedArray[2] = new int[2];
```

Each of the elements is a single-dimensional array of integers. The first element is an array of 5 integers, the second is an array of 4 integers, and the third is an array of 2 integers.

It is also possible to use initializers to fill the array elements with values, in which case you do not need the array size. For example:

```
jaggedArray[0] = new int[] { 1, 3, 5, 7, 9 };
jaggedArray[1] = new int[] { 0, 2, 4, 6 };
jaggedArray[2] = new int[] { 11, 22 };
```

You can also initialize the array upon declaration like this:

```
int[][] jaggedArray2 = new int[][]
{
    new int[] { 1, 3, 5, 7, 9 },
    new int[] { 0, 2, 4, 6 },
    new int[] { 11, 22 }
};
```

You can use the following shorthand form. Notice that you cannot omit the `new` operator from the elements initialization because there is no default initialization for the elements:

```
int[][] jaggedArray3 =
{
    new int[] { 1, 3, 5, 7, 9 },
    new int[] { 0, 2, 4, 6 },
    new int[] { 11, 22 }
};
```

A jagged array is an array of arrays, and therefore its elements are reference types and are initialized to `null`.

You can access individual array elements like these examples:

```
// Assign 77 to the second element ([1]) of the first array ([0]):  
jaggedArray3[0][1] = 77;  
  
// Assign 88 to the second element ([1]) of the third array ([2]):  
jaggedArray3[2][1] = 88;
```

It's possible to mix jagged and multidimensional arrays. The following is a declaration and initialization of a single-dimensional jagged array that contains three two-dimensional array elements of different sizes. For more information, see [Multidimensional Arrays](#).

```
int[,] jaggedArray4 = new int[3][,]  
{  
    new int[,] { {1,3}, {5,7} },  
    new int[,] { {0,2}, {4,6}, {8,10} },  
    new int[,] { {11,22}, {99,88}, {0,9} }  
};
```

You can access individual elements as shown in this example, which displays the value of the element `[1,0]` of the first array (value `5`):

```
System.Console.WriteLine("{0}", jaggedArray4[0][1, 0]);
```

The method `Length` returns the number of arrays contained in the jagged array. For example, assuming you have declared the previous array, this line:

```
System.Console.WriteLine(jaggedArray4.Length);
```

returns a value of 3.

Example

This example builds an array whose elements are themselves arrays. Each one of the array elements has a different size.

```

class ArrayTest
{
    static void Main()
    {
        // Declare the array of two elements.
        int[][] arr = new int[2][];

        // Initialize the elements.
        arr[0] = new int[5] { 1, 3, 5, 7, 9 };
        arr[1] = new int[4] { 2, 4, 6, 8 };

        // Display the array elements.
        for (int i = 0; i < arr.Length; i++)
        {
            System.Console.Write("Element({0}): ", i);

            for (int j = 0; j < arr[i].Length; j++)
            {
                System.Console.Write("{0}{1}", arr[i][j], j == (arr[i].Length - 1) ? "" : " ");
            }
            System.Console.WriteLine();
        }
        // Keep the console window open in debug mode.
        System.Console.WriteLine("Press any key to exit.");
        System.Console.ReadKey();
    }
}
/* Output:
    Element(0): 1 3 5 7 9
    Element(1): 2 4 6 8
*/

```

Using foreach with arrays (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `foreach` statement provides a simple, clean way to iterate through the elements of an array.

For single-dimensional arrays, the `foreach` statement processes elements in increasing index order, starting with index 0 and ending with index `Length - 1`:

```
int[] numbers = { 4, 5, 6, 1, 2, 3, -2, -1, 0 };
foreach (int i in numbers)
{
    System.Console.Write("{0} ", i);
}
// Output: 4 5 6 1 2 3 -2 -1 0
```

For multi-dimensional arrays, elements are traversed such that the indices of the rightmost dimension are increased first, then the next left dimension, and so on to the left:

```
int[,] numbers2D = new int[3, 2] { { 9, 99 }, { 3, 33 }, { 5, 55 } };
// Or use the short form:
// int[,] numbers2D = { { 9, 99 }, { 3, 33 }, { 5, 55 } };

foreach (int i in numbers2D)
{
    System.Console.Write("{0} ", i);
}
// Output: 9 99 3 33 5 55
```

However, with multidimensional arrays, using a nested `for` loop gives you more control over the order in which to process the array elements.

Passing arrays as arguments (C# Programming Guide)

12/28/2021 • 3 minutes to read • [Edit Online](#)

Arrays can be passed as arguments to method parameters. Because arrays are reference types, the method can change the value of the elements.

Passing single-dimensional arrays as arguments

You can pass an initialized single-dimensional array to a method. For example, the following statement sends an array to a print method.

```
int[] theArray = { 1, 3, 5, 7, 9 };  
PrintArray(theArray);
```

The following code shows a partial implementation of the print method.

```
void PrintArray(int[] arr)  
{  
    // Method code.  
}
```

You can initialize and pass a new array in one step, as is shown in the following example.

```
PrintArray(new int[] { 1, 3, 5, 7, 9 });
```

Example

In the following example, an array of strings is initialized and passed as an argument to a `DisplayArray` method for strings. The method displays the elements of the array. Next, the `ChangeArray` method reverses the array elements, and then the `ChangeArrayElements` method modifies the first three elements of the array. After each method returns, the `DisplayArray` method shows that passing an array by value doesn't prevent changes to the array elements.

```

using System;

class ArrayExample
{
    static void DisplayArray(string[] arr) => Console.WriteLine(string.Join(" ", arr));

    // Change the array by reversing its elements.
    static void ChangeArray(string[] arr) => Array.Reverse(arr);

    static void ChangeArrayElements(string[] arr)
    {
        // Change the value of the first three array elements.
        arr[0] = "Mon";
        arr[1] = "Wed";
        arr[2] = "Fri";
    }

    static void Main()
    {
        // Declare and initialize an array.
        string[] weekDays = { "Sun", "Mon", "Tue", "Wed", "Thu", "Fri", "Sat" };
        // Display the array elements.
        DisplayArray(weekDays);
        Console.WriteLine();

        // Reverse the array.
        ChangeArray(weekDays);
        // Display the array again to verify that it stays reversed.
        Console.WriteLine("Array weekDays after the call to ChangeArray:");
        DisplayArray(weekDays);
        Console.WriteLine();

        // Assign new values to individual array elements.
        ChangeArrayElements(weekDays);
        // Display the array again to verify that it has changed.
        Console.WriteLine("Array weekDays after the call to ChangeArrayElements:");
        DisplayArray(weekDays);
    }
}

// The example displays the following output:
//      Sun Mon Tue Wed Thu Fri Sat
//
//      Array weekDays after the call to ChangeArray:
//      Sat Fri Thu Wed Tue Mon Sun
//
//      Array weekDays after the call to ChangeArrayElements:
//      Mon Wed Fri Wed Tue Mon Sun

```

Passing multidimensional arrays as arguments

You pass an initialized multidimensional array to a method in the same way that you pass a one-dimensional array.

```

int[,] theArray = { { 1, 2 }, { 2, 3 }, { 3, 4 } };
Print2DArray(theArray);

```

The following code shows a partial declaration of a print method that accepts a two-dimensional array as its argument.

```
void Print2DArray(int[,] arr)
{
    // Method code.
}
```

You can initialize and pass a new array in one step, as is shown in the following example:

```
Print2DArray(new int[,] { { 1, 2 }, { 3, 4 }, { 5, 6 }, { 7, 8 } });
```

Example

In the following example, a two-dimensional array of integers is initialized and passed to the `Print2DArray` method. The method displays the elements of the array.

```
class ArrayClass2D
{
    static void Print2DArray(int[,] arr)
    {
        // Display the array elements.
        for (int i = 0; i < arr.GetLength(0); i++)
        {
            for (int j = 0; j < arr.GetLength(1); j++)
            {
                System.Console.WriteLine("Element({0},{1})={2}", i, j, arr[i, j]);
            }
        }
    }
    static void Main()
    {
        // Pass the array as an argument.
        Print2DArray(new int[,] { { 1, 2 }, { 3, 4 }, { 5, 6 }, { 7, 8 } });

        // Keep the console window open in debug mode.
        System.Console.WriteLine("Press any key to exit.");
        System.Console.ReadKey();
    }
}
/* Output:
    Element(0,0)=1
    Element(0,1)=2
    Element(1,0)=3
    Element(1,1)=4
    Element(2,0)=5
    Element(2,1)=6
    Element(3,0)=7
    Element(3,1)=8
*/
```

Implicitly Typed Arrays (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

You can create an implicitly-typed array in which the type of the array instance is inferred from the elements specified in the array initializer. The rules for any implicitly-typed variable also apply to implicitly-typed arrays. For more information, see [Implicitly Typed Local Variables](#).

Implicitly-typed arrays are usually used in query expressions together with anonymous types and object and collection initializers.

The following examples show how to create an implicitly-typed array:

```
class ImplicitlyTypedArraySample
{
    static void Main()
    {
        var a = new[] { 1, 10, 100, 1000 }; // int[]
        var b = new[] { "hello", null, "world" }; // string[]

        // single-dimension jagged array
        var c = new[]
        {
            new[] { 1, 2, 3, 4 },
            new[] { 5, 6, 7, 8 }
        };

        // jagged array of strings
        var d = new[]
        {
            new[] { "Luca", "Mads", "Luke", "Dinesh" },
            new[] { "Karen", "Suma", "Frances" }
        };
    }
}
```

In the previous example, notice that with implicitly-typed arrays, no square brackets are used on the left side of the initialization statement. Note also that jagged arrays are initialized by using `new []` just like single-dimension arrays.

Implicitly-typed Arrays in Object Initializers

When you create an anonymous type that contains an array, the array must be implicitly typed in the type's object initializer. In the following example, `contacts` is an implicitly-typed array of anonymous types, each of which contains an array named `PhoneNumbers`. Note that the `var` keyword is not used inside the object initializers.

```
var contacts = new[]  
{  
    new {  
        Name = " Eugene Zabokritski",  
        PhoneNumbers = new[] { "206-555-0108", "425-555-0001" }  
    },  
    new {  
        Name = " Hanying Feng",  
        PhoneNumbers = new[] { "650-555-0199" }  
    }  
};
```

Strings (C# Programming Guide)

12/28/2021 • 13 minutes to read • [Edit Online](#)

A string is an object of type [String](#) whose value is text. Internally, the text is stored as a sequential read-only collection of [Char](#) objects. There is no null-terminating character at the end of a C# string; therefore a C# string can contain any number of embedded null characters ('\0'). The [Length](#) property of a string represents the number of [Char](#) objects it contains, not the number of Unicode characters. To access the individual Unicode code points in a string, use the [StringInfo](#) object.

string vs. System.String

In C#, the `string` keyword is an alias for [String](#). Therefore, `String` and `string` are equivalent, regardless it is recommended to use the provided alias `string` as it works even without `using System;`. The `String` class provides many methods for safely creating, manipulating, and comparing strings. In addition, the C# language overloads some operators to simplify common string operations. For more information about the keyword, see [string](#). For more information about the type and its methods, see [String](#).

Declaring and Initializing Strings

You can declare and initialize strings in various ways, as shown in the following example:

```
// Declare without initializing.
string message1;

// Initialize to null.
string message2 = null;

// Initialize as an empty string.
// Use the Empty constant instead of the literal "".
string message3 = System.String.Empty;

// Initialize with a regular string literal.
string oldPath = "c:\\Program Files\\Microsoft Visual Studio 8.0";

// Initialize with a verbatim string literal.
string newPath = @"c:\Program Files\Microsoft Visual Studio 9.0";

// Use System.String if you prefer.
System.String greeting = "Hello World!";

// In local variables (i.e. within a method body)
// you can use implicit typing.
var temp = "I'm still a strongly-typed System.String!";

// Use a const string to prevent 'message4' from
// being used to store another string value.
const string message4 = "You can't get rid of me!";

// Use the String constructor only when creating
// a string from a char*, char[], or sbyte*. See
// System.String documentation for details.
char[] letters = { 'A', 'B', 'C' };
string alphabet = new string(letters);
```

Note that you do not use the [new](#) operator to create a string object except when initializing the string with an array of chars.

Initialize a string with the [Empty](#) constant value to create a new [String](#) object whose string is of zero length. The string literal representation of a zero-length string is `""`. By initializing strings with the [Empty](#) value instead of [null](#), you can reduce the chances of a [NullReferenceException](#) occurring. Use the static [IsNullOrEmpty\(String\)](#) method to verify the value of a string before you try to access it.

Immutability of String Objects

String objects are *immutable*: they cannot be changed after they have been created. All of the [String](#) methods and C# operators that appear to modify a string actually return the results in a new string object. In the following example, when the contents of `s1` and `s2` are concatenated to form a single string, the two original strings are unmodified. The `+=` operator creates a new string that contains the combined contents. That new object is assigned to the variable `s1`, and the original object that was assigned to `s1` is released for garbage collection because no other variable holds a reference to it.

```
string s1 = "A string is more ";
string s2 = "than the sum of its chars.";

// Concatenate s1 and s2. This actually creates a new
// string object and stores it in s1, releasing the
// reference to the original object.
s1 += s2;

System.Console.WriteLine(s1);
// Output: A string is more than the sum of its chars.
```

Because a string "modification" is actually a new string creation, you must use caution when you create references to strings. If you create a reference to a string, and then "modify" the original string, the reference will continue to point to the original object instead of the new object that was created when the string was modified. The following code illustrates this behavior:

```
string s1 = "Hello ";
string s2 = s1;
s1 += "World";

System.Console.WriteLine(s2);
//Output: Hello
```

For more information about how to create new strings that are based on modifications such as search and replace operations on the original string, see [How to modify string contents](#).

Regular and Verbatim String Literals

Use regular string literals when you must embed escape characters provided by C#, as shown in the following example:

```

string columns = "Column 1\tColumn 2\tColumn 3";
//Output: Column 1      Column 2      Column 3

string rows = "Row 1\r\nRow 2\r\nRow 3";
/* Output:
    Row 1
    Row 2
    Row 3
*/

string title = "\"The \u00C6olean Harp\"", by Samuel Taylor Coleridge";
//Output: "The Æolean Harp", by Samuel Taylor Coleridge

```

Use verbatim strings for convenience and better readability when the string text contains backslash characters, for example in file paths. Because verbatim strings preserve new line characters as part of the string text, they can be used to initialize multiline strings. Use double quotation marks to embed a quotation mark inside a verbatim string. The following example shows some common uses for verbatim strings:

```

string filePath = @"C:\Users\scoleridge\Documents\";
//Output: C:\Users\scoleridge\Documents\

string text = @"My pensive SARA ! thy soft cheek reclined
    Thus on mine arm, most soothing sweet it is
    To sit beside our Cot,...";
/* Output:
My pensive SARA ! thy soft cheek reclined
    Thus on mine arm, most soothing sweet it is
    To sit beside our Cot,...
*/

string quote = @"Her name was ""Sara.""";
//Output: Her name was "Sara."

```

String Escape Sequences

ESCAPE SEQUENCE	CHARACTER NAME	UNICODE ENCODING
\'	Single quote	0x0027
\"	Double quote	0x0022
\\	Backslash	0x005C
\0	Null	0x0000
\a	Alert	0x0007
\b	Backspace	0x0008
\f	Form feed	0x000C
\n	New line	0x000A
\r	Carriage return	0x000D
\t	Horizontal tab	0x0009

ESCAPE SEQUENCE	CHARACTER NAME	UNICODE ENCODING
<code>\v</code>	Vertical tab	0x000B
<code>\u</code>	Unicode escape sequence (UTF-16)	<code>\uHHHH</code> (range: 0000 - FFFF; example: <code>\u00E7</code> = "ç")
<code>\U</code>	Unicode escape sequence (UTF-32)	<code>\U00HHHHHH</code> (range: 000000 - 10FFFF; example: <code>\U0001F47D</code> = "🍷")
<code>\x</code>	Unicode escape sequence similar to <code>"\u"</code> except with variable length	<code>\xH[H][H][H]</code> (range: 0 - FFFF; example: <code>\x00E7</code> or <code>\xE7</code> or <code>\xE7</code> = "ç")

WARNING

When using the `\x` escape sequence and specifying less than 4 hex digits, if the characters that immediately follow the escape sequence are valid hex digits (i.e. 0-9, A-F, and a-f), they will be interpreted as being part of the escape sequence. For example, `\xA1` produces "¡", which is code point U+00A1. However, if the next character is "A" or "a", then the escape sequence will instead be interpreted as being `\xA1A` and produce "■", which is code point U+0A1A. In such cases, specifying all 4 hex digits (e.g. `\x00A1`) will prevent any possible misinterpretation.

NOTE

At compile time, verbatim strings are converted to ordinary strings with all the same escape sequences. Therefore, if you view a verbatim string in the debugger watch window, you will see the escape characters that were added by the compiler, not the verbatim version from your source code. For example, the verbatim string `@ "C:\files.txt"` will appear in the watch window as `"C:\\files.txt"`.

Format Strings

A format string is a string whose contents are determined dynamically at run time. Format strings are created by embedding *interpolated expressions* or placeholders inside of braces within a string. Everything inside the braces (`{...}`) will be resolved to a value and output as a formatted string at run time. There are two methods to create format strings: string interpolation and composite formatting.

String Interpolation

Available in C# 6.0 and later, *interpolated strings* are identified by the `$` special character and include interpolated expressions in braces. If you are new to string interpolation, see the [String interpolation - C# interactive tutorial](#) for a quick overview.

Use string interpolation to improve the readability and maintainability of your code. String interpolation achieves the same results as the `String.Format` method, but improves ease of use and inline clarity.

```
var jh = (firstName: "Jupiter", lastName: "Hammon", born: 1711, published: 1761);
Console.WriteLine($"{jh.firstName} {jh.lastName} was an African American poet born in {jh.born}.");
Console.WriteLine($"He was first published in {jh.published} at the age of {jh.published - jh.born}.");
Console.WriteLine($"He'd be over {Math.Round((2018d - jh.born) / 100d) * 100d} years old today.");

// Output:
// Jupiter Hammon was an African American poet born in 1711.
// He was first published in 1761 at the age of 50.
// He'd be over 300 years old today.
```

Beginning with C# 10, you can use string interpolation to initialize a constant string when all the expressions used for placeholders are also constant strings.

Composite Formatting

The [String.Format](#) utilizes placeholders in braces to create a format string. This example results in similar output to the string interpolation method used above.

```
var pw = (firstName: "Phillis", lastName: "Wheatley", born: 1753, published: 1773);
Console.WriteLine("{0} {1} was an African American poet born in {2}.", pw.firstName, pw.lastName, pw.born);
Console.WriteLine("She was first published in {0} at the age of {1}.", pw.published, pw.published - pw.born);
Console.WriteLine("She'd be over {0} years old today.", Math.Round((2018d - pw.born) / 100d) * 100d);

// Output:
// Phillis Wheatley was an African American poet born in 1753.
// She was first published in 1773 at the age of 20.
// She'd be over 300 years old today.
```

For more information on formatting .NET types see [Formatting Types in .NET](#).

Substrings

A substring is any sequence of characters that is contained in a string. Use the [Substring](#) method to create a new string from a part of the original string. You can search for one or more occurrences of a substring by using the [IndexOf](#) method. Use the [Replace](#) method to replace all occurrences of a specified substring with a new string. Like the [Substring](#) method, [Replace](#) actually returns a new string and does not modify the original string. For more information, see [How to search strings](#) and [How to modify string contents](#).

```
string s3 = "Visual C# Express";
System.Console.WriteLine(s3.Substring(7, 2));
// Output: "C#"

System.Console.WriteLine(s3.Replace("C#", "Basic"));
// Output: "Visual Basic Express"

// Index values are zero-based
int index = s3.IndexOf("C");
// index = 7
```

Accessing Individual Characters

You can use array notation with an index value to acquire read-only access to individual characters, as in the following example:

```
string s5 = "Printing backwards";

for (int i = 0; i < s5.Length; i++)
{
    System.Console.Write(s5[s5.Length - i - 1]);
}
// Output: "sdrawkcb gnitnirP"
```

If the [String](#) methods do not provide the functionality that you must have to modify individual characters in a string, you can use a [StringBuilder](#) object to modify the individual chars "in-place", and then create a new string to store the results by using the [StringBuilder](#) methods. In the following example, assume that you must modify the original string in a particular way and then store the results for future use:

```
string question = "hOW DOES mICROSOFT wORD DEAL WITH THE cAPS LOCK KEY?";
System.Text.StringBuilder sb = new System.Text.StringBuilder(question);

for (int j = 0; j < sb.Length; j++)
{
    if (System.Char.IsLower(sb[j]) == true)
        sb[j] = System.Char.ToUpper(sb[j]);
    else if (System.Char.IsUpper(sb[j]) == true)
        sb[j] = System.Char.ToLower(sb[j]);
}
// Store the new string.
string corrected = sb.ToString();
System.Console.WriteLine(corrected);
// Output: How does Microsoft Word deal with the Caps Lock key?
```

Null Strings and Empty Strings

An empty string is an instance of a [System.String](#) object that contains zero characters. Empty strings are used often in various programming scenarios to represent a blank text field. You can call methods on empty strings because they are valid [System.String](#) objects. Empty strings are initialized as follows:

```
string s = String.Empty;
```

By contrast, a null string does not refer to an instance of a [System.String](#) object and any attempt to call a method on a null string causes a [NullReferenceException](#). However, you can use null strings in concatenation and comparison operations with other strings. The following examples illustrate some cases in which a reference to a null string does and does not cause an exception to be thrown:

```

static void Main()
{
    string str = "hello";
    string nullStr = null;
    string emptyStr = String.Empty;

    string tempStr = str + nullStr;
    // Output of the following line: hello
    Console.WriteLine(tempStr);

    bool b = (emptyStr == nullStr);
    // Output of the following line: False
    Console.WriteLine(b);

    // The following line creates a new empty string.
    string newStr = emptyStr + nullStr;

    // Null strings and empty strings behave differently. The following
    // two lines display 0.
    Console.WriteLine(emptyStr.Length);
    Console.WriteLine(newStr.Length);
    // The following line raises a NullReferenceException.
    //Console.WriteLine(nullStr.Length);

    // The null character can be displayed and counted, like other chars.
    string s1 = "\x0" + "abc";
    string s2 = "abc" + "\x0";
    // Output of the following line: * abc*
    Console.WriteLine("'" + s1 + "'");
    // Output of the following line: *abc *
    Console.WriteLine("'" + s2 + "'");
    // Output of the following line: 4
    Console.WriteLine(s2.Length);
}

```

Using StringBuilder for Fast String Creation

String operations in .NET are highly optimized and in most cases do not significantly impact performance. However, in some scenarios such as tight loops that are executing many hundreds or thousands of times, string operations can affect performance. The [StringBuilder](#) class creates a string buffer that offers better performance if your program performs many string manipulations. The [StringBuilder](#) string also enables you to reassign individual characters, something the built-in string data type does not support. This code, for example, changes the content of a string without creating a new string:

```

System.Text.StringBuilder sb = new System.Text.StringBuilder("Rat: the ideal pet");
sb[0] = 'C';
System.Console.WriteLine(sb.ToString());
System.Console.ReadLine();

//Outputs Cat: the ideal pet

```

In this example, a [StringBuilder](#) object is used to create a string from a set of numeric types:

```

using System;
using System.Text;

namespace CSRefStrings
{
    class TestStringBuilder
    {
        static void Main()
        {
            var sb = new StringBuilder();

            // Create a string composed of numbers 0 - 9
            for (int i = 0; i < 10; i++)
            {
                sb.Append(i.ToString());
            }
            Console.WriteLine(sb); // displays 0123456789

            // Copy one character of the string (not possible with a System.String)
            sb[0] = sb[9];

            Console.WriteLine(sb); // displays 9123456789
            Console.WriteLine();
        }
    }
}

```

Strings, Extension Methods and LINQ

Because the [String](#) type implements [IEnumerable<T>](#), you can use the extension methods defined in the [Enumerable](#) class on strings. To avoid visual clutter, these methods are excluded from IntelliSense for the [String](#) type, but they are available nevertheless. You can also use LINQ query expressions on strings. For more information, see [LINQ and Strings](#).

How to determine whether a string represents a numeric value (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

To determine whether a string is a valid representation of a specified numeric type, use the static `TryParse` method that is implemented by all primitive numeric types and also by types such as `DateTime` and `IPAddress`. The following example shows how to determine whether "108" is a valid `int`.

```
int i = 0;
string s = "108";
bool result = int.TryParse(s, out i); //i now = 108
```

If the string contains nonnumeric characters or the numeric value is too large or too small for the particular type you have specified, `TryParse` returns false and sets the out parameter to zero. Otherwise, it returns true and sets the out parameter to the numeric value of the string.

NOTE

A string may contain only numeric characters and still not be valid for the type whose `TryParse` method that you use. For example, "256" is not a valid value for `byte` but it is valid for `int`. "98.6" is not a valid value for `int` but it is a valid `decimal`.

Example

The following examples show how to use `TryParse` with string representations of `long`, `byte`, and `decimal` values.

```
string numString = "1287543"; //"1287543.0" will return false for a long
long number1 = 0;
bool canConvert = long.TryParse(numString, out number1);
if (canConvert == true)
    Console.WriteLine("number1 now = {0}", number1);
else
    Console.WriteLine("numString is not a valid long");

byte number2 = 0;
numString = "255"; // A value of 256 will return false
canConvert = byte.TryParse(numString, out number2);
if (canConvert == true)
    Console.WriteLine("number2 now = {0}", number2);
else
    Console.WriteLine("numString is not a valid byte");

decimal number3 = 0;
numString = "27.3"; //"27" is also a valid decimal
canConvert = decimal.TryParse(numString, out number3);
if (canConvert == true)
    Console.WriteLine("number3 now = {0}", number3);
else
    Console.WriteLine("number3 is not a valid decimal");
```

Robust Programming

Primitive numeric types also implement the `Parse` static method, which throws an exception if the string is not a valid number. `TryParse` is generally more efficient because it just returns false if the number is not valid.

.NET Security

Always use the `TryParse` or `Parse` methods to validate user input from controls such as text boxes and combo boxes.

Indexers (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Indexers allow instances of a class or struct to be indexed just like arrays. The indexed value can be set or retrieved without explicitly specifying a type or instance member. Indexers resemble [properties](#) except that their accessors take parameters.

The following example defines a generic class with simple [get](#) and [set](#) accessor methods to assign and retrieve values. The `Program` class creates an instance of this class for storing strings.

```
using System;

class SampleCollection<T>
{
    // Declare an array to store the data elements.
    private T[] arr = new T[100];

    // Define the indexer to allow client code to use [] notation.
    public T this[int i]
    {
        get { return arr[i]; }
        set { arr[i] = value; }
    }
}

class Program
{
    static void Main()
    {
        var stringCollection = new SampleCollection<string>();
        stringCollection[0] = "Hello, World";
        Console.WriteLine(stringCollection[0]);
    }
}

// The example displays the following output:
//      Hello, World.
```

NOTE

For more examples, see [Related Sections](#).

Expression Body Definitions

It is common for an indexer's get or set accessor to consist of a single statement that either returns or sets a value. Expression-bodied members provide a simplified syntax to support this scenario. Starting with C# 6, a read-only indexer can be implemented as an expression-bodied member, as the following example shows.

```

using System;

class SampleCollection<T>
{
    // Declare an array to store the data elements.
    private T[] arr = new T[100];
    int nextIndex = 0;

    // Define the indexer to allow client code to use [] notation.
    public T this[int i] => arr[i];

    public void Add(T value)
    {
        if (nextIndex >= arr.Length)
            throw new IndexOutOfRangeException($"The collection can hold only {arr.Length} elements.");
        arr[nextIndex++] = value;
    }
}

class Program
{
    static void Main()
    {
        var stringCollection = new SampleCollection<string>();
        stringCollection.Add("Hello, World");
        System.Console.WriteLine(stringCollection[0]);
    }
}
// The example displays the following output:
//      Hello, World.

```

Note that `=>` introduces the expression body, and that the `get` keyword is not used.

Starting with C# 7.0, both the get and set accessor can be implemented as expression-bodied members. In this case, both `get` and `set` keywords must be used. For example:

```

using System;

class SampleCollection<T>
{
    // Declare an array to store the data elements.
    private T[] arr = new T[100];

    // Define the indexer to allow client code to use [] notation.
    public T this[int i]
    {
        get => arr[i];
        set => arr[i] = value;
    }
}

class Program
{
    static void Main()
    {
        var stringCollection = new SampleCollection<string>();
        stringCollection[0] = "Hello, World.";
        Console.WriteLine(stringCollection[0]);
    }
}
// The example displays the following output:
//      Hello, World.

```

Indexers Overview

- Indexers enable objects to be indexed in a similar manner to arrays.
- A `get` accessor returns a value. A `set` accessor assigns a value.
- The `this` keyword is used to define the indexer.
- The `value` keyword is used to define the value being assigned by the `set` accessor.
- Indexers do not have to be indexed by an integer value; it is up to you how to define the specific look-up mechanism.
- Indexers can be overloaded.
- Indexers can have more than one formal parameter, for example, when accessing a two-dimensional array.

Using indexers (C# Programming Guide)

12/28/2021 • 6 minutes to read • [Edit Online](#)

Indexers are a syntactic convenience that enable you to create a [class](#), [struct](#), or [interface](#) that client applications can access as an array. The compiler will generate an `Item` property (or an alternatively named property if `IndexerNameAttribute` is present), and the appropriate accessor methods. Indexers are most frequently implemented in types whose primary purpose is to encapsulate an internal collection or array. For example, suppose you have a class `TempRecord` that represents the temperature in Fahrenheit as recorded at 10 different times during a 24-hour period. The class contains a `temps` array of type `float[]` to store the temperature values. By implementing an indexer in this class, clients can access the temperatures in a `TempRecord` instance as `float temp = tempRecord[4]` instead of as `float temp = tempRecord.temps[4]`. The indexer notation not only simplifies the syntax for client applications; it also makes the class, and its purpose more intuitive for other developers to understand.

To declare an indexer on a class or struct, use the `this` keyword, as the following example shows:

```
// Indexer declaration
public int this[int index]
{
    // get and set accessors
}
```

IMPORTANT

Declaring an indexer will automatically generate a property named `Item` on the object. The `Item` property is not directly accessible from the instance [member access expression](#). Additionally, if you add your own `Item` property to an object with an indexer, you'll get a [CS0102 compiler error](#). To avoid this error, use the `IndexerNameAttribute` to rename the indexer as detailed below.

Remarks

The type of an indexer and the type of its parameters must be at least as accessible as the indexer itself. For more information about accessibility levels, see [Access Modifiers](#).

For more information about how to use indexers with an interface, see [Interface Indexers](#).

The signature of an indexer consists of the number and types of its formal parameters. It doesn't include the indexer type or the names of the formal parameters. If you declare more than one indexer in the same class, they must have different signatures.

An indexer value is not classified as a variable; therefore, you cannot pass an indexer value as a [ref](#) or [out](#) parameter.

To provide the indexer with a name that other languages can use, use `System.Runtime.CompilerServices.IndexerNameAttribute`, as the following example shows:

```
// Indexer declaration
[System.Runtime.CompilerServices.IndexerName("TheItem")]
public int this[int index]
{
    // get and set accessors
}
```

This indexer will have the name `TheItem`, as it is overridden by the indexer name attribute. By default, the indexer name is `Item`.

Example 1

The following example shows how to declare a private array field, `temps`, and an indexer. The indexer enables direct access to the instance `tempRecord[i]`. The alternative to using the indexer is to declare the array as a [public](#) member and access its members, `tempRecord.temps[i]`, directly.

```
public class TempRecord
{
    // Array of temperature values
    float[] temps = new float[10]
    {
        56.2F, 56.7F, 56.5F, 56.9F, 58.8F,
        61.3F, 65.9F, 62.1F, 59.2F, 57.5F
    };

    // To enable client code to validate input
    // when accessing your indexer.
    public int Length => temps.Length;

    // Indexer declaration.
    // If index is out of range, the temps array will throw the exception.
    public float this[int index]
    {
        get => temps[index];
        set => temps[index] = value;
    }
}
```

Notice that when an indexer's access is evaluated, for example, in a `Console.Write` statement, the [get](#) accessor is invoked. Therefore, if no `get` accessor exists, a compile-time error occurs.

```

using System;

class Program
{
    static void Main()
    {
        var tempRecord = new TempRecord();

        // Use the indexer's set accessor
        tempRecord[3] = 58.3F;
        tempRecord[5] = 60.1F;

        // Use the indexer's get accessor
        for (int i = 0; i < 10; i++)
        {
            Console.WriteLine($"Element #{i} = {tempRecord[i]}");
        }

        // Keep the console window open in debug mode.
        Console.WriteLine("Press any key to exit.");
        Console.ReadKey();
    }
    /* Output:
        Element #0 = 56.2
        Element #1 = 56.7
        Element #2 = 56.5
        Element #3 = 58.3
        Element #4 = 58.8
        Element #5 = 60.1
        Element #6 = 65.9
        Element #7 = 62.1
        Element #8 = 59.2
        Element #9 = 57.5
    */
}

```

Indexing using other values

C# doesn't limit the indexer parameter type to integer. For example, it may be useful to use a string with an indexer. Such an indexer might be implemented by searching for the string in the collection, and returning the appropriate value. As accessors can be overloaded, the string and integer versions can coexist.

Example 2

The following example declares a class that stores the days of the week. A `get` accessor takes a string, the name of a day, and returns the corresponding integer. For example, "Sunday" returns 0, "Monday" returns 1, and so on.

```

using System;

// Using a string as an indexer value
class DayCollection
{
    string[] days = { "Sun", "Mon", "Tues", "Wed", "Thurs", "Fri", "Sat" };

    // Indexer with only a get accessor with the expression-bodied definition:
    public int this[string day] => FindDayIndex(day);

    private int FindDayIndex(string day)
    {
        for (int j = 0; j < days.Length; j++)
        {
            if (days[j] == day)
            {
                return j;
            }
        }

        throw new ArgumentOutOfRangeException(
            nameof(day),
            $"Day {day} is not supported.\nDay input must be in the form \"Sun\", \"Mon\", etc");
    }
}

```

Consuming example 2

```

using System;

class Program
{
    static void Main(string[] args)
    {
        var week = new DayCollection();
        Console.WriteLine(week["Fri"]);

        try
        {
            Console.WriteLine(week["Made-up day"]);
        }
        catch (ArgumentOutOfRangeException e)
        {
            Console.WriteLine($"Not supported input: {e.Message}");
        }
    }
}
// Output:
// 5
// Not supported input: Day Made-up day is not supported.
// Day input must be in the form "Sun", "Mon", etc (Parameter 'day')

```

Example 3

The following example declares a class that stores the days of the week using the [System.DayOfWeek](#) enum. A `get` accessor takes a `DayOfWeek`, the value of a day, and returns the corresponding integer. For example, `DayOfWeek.Sunday` returns 0, `DayOfWeek.Monday` returns 1, and so on.

```

using System;
using Day = System.DayOfWeek;

class DayOfWeekCollection
{
    Day[] days =
    {
        Day.Sunday, Day.Monday, Day.Tuesday, Day.Wednesday,
        Day.Thursday, Day.Friday, Day.Saturday
    };

    // Indexer with only a get accessor with the expression-bodied definition:
    public int this[Day day] => FindDayIndex(day);

    private int FindDayIndex(Day day)
    {
        for (int j = 0; j < days.Length; j++)
        {
            if (days[j] == day)
            {
                return j;
            }
        }
        throw new ArgumentOutOfRangeException(
            nameof(day),
            $"Day {day} is not supported.\nDay input must be a defined System.DayOfWeek value.");
    }
}

```

Consuming example 3

```

using System;

class Program
{
    static void Main()
    {
        var week = new DayOfWeekCollection();
        Console.WriteLine(week[DayOfWeek.Friday]);

        try
        {
            Console.WriteLine(week[(DayOfWeek)43]);
        }
        catch (ArgumentOutOfRangeException e)
        {
            Console.WriteLine($"Not supported input: {e.Message}");
        }
    }
    // Output:
    // 5
    // Not supported input: Day 43 is not supported.
    // Day input must be a defined System.DayOfWeek value. (Parameter 'day')
}

```

Robust programming

There are two main ways in which the security and reliability of indexers can be improved:

- Be sure to incorporate some type of error-handling strategy to handle the chance of client code passing in an invalid index value. In the first example earlier in this topic, the TempRecord class provides a Length property that enables the client code to verify the input before passing it to the indexer. You can also put the error handling code inside the indexer itself. Be sure to document for users any exceptions that you

throw inside an indexer accessor.

- Set the accessibility of the [get](#) and [set](#) accessors to be as restrictive as is reasonable. This is important for the `set` accessor in particular. For more information, see [Restricting Accessor Accessibility](#).

Indexers in Interfaces (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Indexers can be declared on an [interface](#). Accessors of interface indexers differ from the accessors of [class](#) indexers in the following ways:

- Interface accessors do not use modifiers.
- An interface accessor typically does not have a body.

The purpose of the accessor is to indicate whether the indexer is read-write, read-only, or write-only. You may provide an implementation for an indexer defined in an interface, but this is rare. Indexers typically define an API to access data fields, and data fields cannot be defined in an interface.

The following is an example of an interface indexer accessor:

```
public interface ISomeInterface
{
    //...

    // Indexer declaration:
    string this[int index]
    {
        get;
        set;
    }
}
```

The signature of an indexer must differ from the signatures of all other indexers declared in the same interface.

Example

The following example shows how to implement interface indexers.

```
// Indexer on an interface:
public interface IIndexInterface
{
    // Indexer declaration:
    int this[int index]
    {
        get;
        set;
    }
}

// Implementing the interface.
class IndexerClass : IIndexInterface
{
    private int[] arr = new int[100];
    public int this[int index] // indexer declaration
    {
        // The arr object will throw IndexOutOfRangeException exception.
        get => arr[index];
        set => arr[index] = value;
    }
}
```

```

IndexerClass test = new IndexerClass();
System.Random rand = new System.Random();
// Call the indexer to initialize its elements.
for (int i = 0; i < 10; i++)
{
    test[i] = rand.Next();
}
for (int i = 0; i < 10; i++)
{
    System.Console.WriteLine($"Element #{i} = {test[i]}");
}

/* Sample output:
    Element #0 = 360877544
    Element #1 = 327058047
    Element #2 = 1913480832
    Element #3 = 1519039937
    Element #4 = 601472233
    Element #5 = 323352310
    Element #6 = 1422639981
    Element #7 = 1797892494
    Element #8 = 875761049
    Element #9 = 393083859
*/

```

In the preceding example, you could use the explicit interface member implementation by using the fully qualified name of the interface member. For example

```

string IIndexInterface.this[int index]
{
}

```

However, the fully qualified name is only needed to avoid ambiguity when the class is implementing more than one interface with the same indexer signature. For example, if an `Employee` class is implementing two interfaces, `ICitizen` and `IEmployee`, and both interfaces have the same indexer signature, the explicit interface member implementation is necessary. That is, the following indexer declaration:

```

string IEmployee.this[int index]
{
}

```

implements the indexer on the `IEmployee` interface, while the following declaration:

```

string ICitizen.this[int index]
{
}

```

implements the indexer on the `ICitizen` interface.

Comparison Between Properties and Indexers (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Indexers are like properties. Except for the differences shown in the following table, all the rules that are defined for property accessors apply to indexer accessors also.

PROPERTY	INDEXER
Allows methods to be called as if they were public data members.	Allows elements of an internal collection of an object to be accessed by using array notation on the object itself.
Accessed through a simple name.	Accessed through an index.
Can be a static or an instance member.	Must be an instance member.
A get accessor of a property has no parameters.	A <code>get</code> accessor of an indexer has the same formal parameter list as the indexer.
A set accessor of a property contains the implicit <code>value</code> parameter.	A <code>set</code> accessor of an indexer has the same formal parameter list as the indexer, and also to the value parameter.
Supports shortened syntax with Auto-Implemented Properties .	Supports expression bodied members for get only indexers.

Events (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Events enable a [class](#) or object to notify other classes or objects when something of interest occurs. The class that sends (or *raises*) the event is called the *publisher* and the classes that receive (or *handle*) the event are called *subscribers*.

In a typical C# Windows Forms or Web application, you subscribe to events raised by controls such as buttons and list boxes. You can use the Visual C# integrated development environment (IDE) to browse the events that a control publishes and select the ones that you want to handle. The IDE provides an easy way to automatically add an empty event handler method and the code to subscribe to the event. For more information, see [How to subscribe to and unsubscribe from events](#).

Events Overview

Events have the following properties:

- The publisher determines when an event is raised; the subscribers determine what action is taken in response to the event.
- An event can have multiple subscribers. A subscriber can handle multiple events from multiple publishers.
- Events that have no subscribers are never raised.
- Events are typically used to signal user actions such as button clicks or menu selections in graphical user interfaces.
- When an event has multiple subscribers, the event handlers are invoked synchronously when an event is raised. To invoke events asynchronously, see [Calling Synchronous Methods Asynchronously](#).
- In the .NET class library, events are based on the [EventHandler](#) delegate and the [EventArgs](#) base class.

How to subscribe to and unsubscribe from events (C# Programming Guide)

12/28/2021 • 3 minutes to read • [Edit Online](#)

You subscribe to an event that is published by another class when you want to write custom code that is called when that event is raised. For example, you might subscribe to a button's `click` event in order to make your application do something useful when the user clicks the button.

To subscribe to events by using the Visual Studio IDE

1. If you cannot see the **Properties** window, in **Design** view, right-click the form or control for which you want to create an event handler, and select **Properties**.
2. On top of the **Properties** window, click the **Events** icon.
3. Double-click the event that you want to create, for example the `Load` event.

Visual C# creates an empty event handler method and adds it to your code. Alternatively you can add the code manually in **Code** view. For example, the following lines of code declare an event handler method that will be called when the `Form` class raises the `Load` event.

```
private void Form1_Load(object sender, System.EventArgs e)
{
    // Add your form load event handling code here.
}
```

The line of code that is required to subscribe to the event is also automatically generated in the `InitializeComponent` method in the `Form1.Designer.cs` file in your project. It resembles this:

```
this.Load += new System.EventHandler(this.Form1_Load);
```

To subscribe to events programmatically

1. Define an event handler method whose signature matches the delegate signature for the event. For example, if the event is based on the `EventHandler` delegate type, the following code represents the method stub:

```
void HandleCustomEvent(object sender, CustomEventArgs a)
{
    // Do something useful here.
}
```

2. Use the addition assignment operator (`+=`) to attach an event handler to the event. In the following example, assume that an object named `publisher` has an event named `RaiseCustomEvent`. Note that the subscriber class needs a reference to the publisher class in order to subscribe to its events.

```
publisher.RaiseCustomEvent += HandleCustomEvent;
```

You can also use a [lambda expression](#) to specify an event handler:

```
public Form1()
{
    InitializeComponent();
    this.Click += (s,e) =>
    {
        MessageBox.Show(((MouseEventArgs)e).Location.ToString());
    };
}
```

To subscribe to events by using an anonymous function

If you don't have to unsubscribe from an event later, you can use the addition assignment operator (`+=`) to attach an anonymous function as an event handler. In the following example, assume that an object named `publisher` has an event named `RaiseCustomEvent` and that a `CustomEventArgs` class has also been defined to carry some kind of specialized event information. Note that the subscriber class needs a reference to `publisher` in order to subscribe to its events.

```
publisher.RaiseCustomEvent += (object o, CustomEventArgs e) =>
{
    string s = o.ToString() + " " + e.ToString();
    Console.WriteLine(s);
};
```

You cannot easily unsubscribe from an event if you used an anonymous function to subscribe to it. To unsubscribe in this scenario, go back to the code where you subscribe to the event, store the anonymous function in a delegate variable, and then add the delegate to the event. We recommend that you don't use anonymous functions to subscribe to events if you have to unsubscribe from the event at some later point in your code. For more information about anonymous functions, see [Lambda expressions](#).

Unsubscribing

To prevent your event handler from being invoked when the event is raised, unsubscribe from the event. In order to prevent resource leaks, you should unsubscribe from events before you dispose of a subscriber object. Until you unsubscribe from an event, the multicast delegate that underlies the event in the publishing object has a reference to the delegate that encapsulates the subscriber's event handler. As long as the publishing object holds that reference, garbage collection will not delete your subscriber object.

To unsubscribe from an event

- Use the subtraction assignment operator (`-=`) to unsubscribe from an event:

```
publisher.RaiseCustomEvent -= HandleCustomEvent;
```

When all subscribers have unsubscribed from an event, the event instance in the publisher class is set to `null`.

How to publish events that conform to .NET Guidelines (C# Programming Guide)

12/28/2021 • 3 minutes to read • [Edit Online](#)

The following procedure demonstrates how to add events that follow the standard .NET pattern to your classes and structs. All events in the .NET class library are based on the [EventHandler](#) delegate, which is defined as follows:

```
public delegate void EventHandler(object sender, EventArgs e);
```

NOTE

.NET Framework 2.0 introduces a generic version of this delegate, [EventHandler<TEventArgs>](#). The following examples show how to use both versions.

Although events in classes that you define can be based on any valid delegate type, even delegates that return a value, it is generally recommended that you base your events on the .NET pattern by using [EventHandler](#), as shown in the following example.

The name `EventHandler` can lead to a bit of confusion as it doesn't actually handle the event. The [EventHandler](#), and generic [EventHandler<TEventArgs>](#) are delegate types. A method or lambda expression whose signature matches the delegate definition is the *event handler* and will be invoked when the event is raised.

Publish events based on the EventHandler pattern

1. (Skip this step and go to Step 3a if you do not have to send custom data with your event.) Declare the class for your custom data at a scope that is visible to both your publisher and subscriber classes. Then add the required members to hold your custom event data. In this example, a simple string is returned.

```
public class CustomEventArgs : EventArgs
{
    public CustomEventArgs(string message)
    {
        Message = message;
    }

    public string Message { get; set; }
}
```

2. (Skip this step if you are using the generic version of [EventHandler<TEventArgs>](#).) Declare a delegate in your publishing class. Give it a name that ends with `EventHandler`. The second parameter specifies your custom `EventArgs` type.

```
public delegate void CustomEventHandler(object sender, CustomEventArgs args);
```

3. Declare the event in your publishing class by using one of the following steps.
 - a. If you have no custom EventArgs class, your Event type will be the non-generic EventHandler delegate. You do not have to declare the delegate because it is already declared in the [System](#)

namespace that is included when you create your C# project. Add the following code to your publisher class.

```
public event EventHandler RaiseCustomEvent;
```

- b. If you are using the non-generic version of [EventHandler](#) and you have a custom class derived from [EventArgs](#), declare your event inside your publishing class and use your delegate from step 2 as the type.

```
public event CustomEventHandler RaiseCustomEvent;
```

- c. If you are using the generic version, you do not need a custom delegate. Instead, in your publishing class, you specify your event type as `EventHandler<CustomEventArgs>`, substituting the name of your own class between the angle brackets.

```
public event EventHandler<CustomEventArgs> RaiseCustomEvent;
```

Example

The following example demonstrates the previous steps by using a custom `EventArgs` class and `EventHandler<TEventArgs>` as the event type.

```
using System;

namespace DotNetEvents
{
    // Define a class to hold custom event info
    public class CustomEventArgs : EventArgs
    {
        public CustomEventArgs(string message)
        {
            Message = message;
        }

        public string Message { get; set; }
    }

    // Class that publishes an event
    class Publisher
    {
        // Declare the event using EventHandler<T>
        public event EventHandler<CustomEventArgs> RaiseCustomEvent;

        public void DoSomething()
        {
            // Write some code that does something useful here
            // then raise the event. You can also raise an event
            // before you execute a block of code.
            OnRaiseCustomEvent(new CustomEventArgs("Event triggered"));
        }

        // Wrap event invocations inside a protected virtual method
        // to allow derived classes to override the event invocation behavior
        protected virtual void OnRaiseCustomEvent(CustomEventArgs e)
        {
            // Make a temporary copy of the event to avoid possibility of
            // a race condition if the last subscriber unsubscribes
            // immediately after the null check and before the event is raised.
            EventHandler<CustomEventArgs> raiseEvent = RaiseCustomEvent;
```

```

        // Event will be null if there are no subscribers
        if (raiseEvent != null)
        {
            // Format the string to send inside the CustomEventArgs parameter
            e.Message += $" at {DateTime.Now}";

            // Call to raise the event.
            raiseEvent(this, e);
        }
    }
}

//Class that subscribes to an event
class Subscriber
{
    private readonly string _id;

    public Subscriber(string id, Publisher pub)
    {
        _id = id;

        // Subscribe to the event
        pub.RaiseCustomEvent += HandleCustomEvent;
    }

    // Define what actions to take when the event is raised.
    void HandleCustomEvent(object sender, CustomEventArgs e)
    {
        Console.WriteLine($"{_id} received this message: {e.Message}");
    }
}

class Program
{
    static void Main()
    {
        var pub = new Publisher();
        var sub1 = new Subscriber("sub1", pub);
        var sub2 = new Subscriber("sub2", pub);

        // Call the method that raises the event.
        pub.DoSomething();

        // Keep the console window open
        Console.WriteLine("Press any key to continue...");
        Console.ReadLine();
    }
}

```

How to raise base class events in derived classes (C# Programming Guide)

12/28/2021 • 3 minutes to read • [Edit Online](#)

The following simple example shows the standard way to declare events in a base class so that they can also be raised from derived classes. This pattern is used extensively in Windows Forms classes in the .NET class libraries.

When you create a class that can be used as a base class for other classes, you should consider the fact that events are a special type of delegate that can only be invoked from within the class that declared them. Derived classes cannot directly invoke events that are declared within the base class. Although sometimes you may want an event that can only be raised by the base class, most of the time, you should enable the derived class to invoke base class events. To do this, you can create a protected invoking method in the base class that wraps the event. By calling or overriding this invoking method, derived classes can invoke the event indirectly.

NOTE

Do not declare virtual events in a base class and override them in a derived class. The C# compiler does not handle these correctly and it is unpredictable whether a subscriber to the derived event will actually be subscribing to the base class event.

Example

```
namespace BaseClassEvents
{
    // Special EventArgs class to hold info about Shapes.
    public class ShapeEventArgs : EventArgs
    {
        public ShapeEventArgs(double area)
        {
            NewArea = area;
        }

        public double NewArea { get; }
    }

    // Base class event publisher
    public abstract class Shape
    {
        protected double _area;

        public double Area
        {
            get => _area;
            set => _area = value;
        }

        // The event. Note that by using the generic EventHandler<T> event type
        // we do not need to declare a separate delegate type.
        public event EventHandler<ShapeEventArgs> ShapeChanged;

        public abstract void Draw();

        //The event-invoking method that derived classes can override.
        protected virtual void OnShapeChanged(ShapeEventArgs e)
        {
        }
    }
}
```

```

        // Safely raise the event for all subscribers
        ShapeChanged?.Invoke(this, e);
    }
}

public class Circle : Shape
{
    private double _radius;

    public Circle(double radius)
    {
        _radius = radius;
        _area = 3.14 * _radius * _radius;
    }

    public void Update(double d)
    {
        _radius = d;
        _area = 3.14 * _radius * _radius;
        OnShapeChanged(new ShapeEventArgs(_area));
    }

    protected override void OnShapeChanged(ShapeEventArgs e)
    {
        // Do any circle-specific processing here.

        // Call the base class event invocation method.
        base.OnShapeChanged(e);
    }

    public override void Draw()
    {
        Console.WriteLine("Drawing a circle");
    }
}

public class Rectangle : Shape
{
    private double _length;
    private double _width;

    public Rectangle(double length, double width)
    {
        _length = length;
        _width = width;
        _area = _length * _width;
    }

    public void Update(double length, double width)
    {
        _length = length;
        _width = width;
        _area = _length * _width;
        OnShapeChanged(new ShapeEventArgs(_area));
    }

    protected override void OnShapeChanged(ShapeEventArgs e)
    {
        // Do any rectangle-specific processing here.

        // Call the base class event invocation method.
        base.OnShapeChanged(e);
    }

    public override void Draw()
    {
        Console.WriteLine("Drawing a rectangle");
    }
}

```

```

    }

    // Represents the surface on which the shapes are drawn
    // Subscribes to shape events so that it knows
    // when to redraw a shape.
    public class ShapeContainer
    {
        private readonly List<Shape> _list;

        public ShapeContainer()
        {
            _list = new List<Shape>();
        }

        public void AddShape(Shape shape)
        {
            _list.Add(shape);

            // Subscribe to the base class event.
            shape.ShapeChanged += HandleShapeChanged;
        }

        // ...Other methods to draw, resize, etc.

        private void HandleShapeChanged(object sender, ShapeEventArgs e)
        {
            if (sender is Shape shape)
            {
                // Diagnostic message for demonstration purposes.
                Console.WriteLine($"Received event. Shape area is now {e.NewArea}");

                // Redraw the shape here.
                shape.Draw();
            }
        }
    }

    class Test
    {
        static void Main()
        {
            //Create the event publishers and subscriber
            var circle = new Circle(54);
            var rectangle = new Rectangle(12, 9);
            var container = new ShapeContainer();

            // Add the shapes to the container.
            container.AddShape(circle);
            container.AddShape(rectangle);

            // Cause some events to be raised.
            circle.Update(57);
            rectangle.Update(7, 7);

            // Keep the console window open in debug mode.
            Console.WriteLine("Press any key to continue...");
            Console.ReadKey();
        }
    }
}

/* Output:
    Received event. Shape area is now 10201.86
    Drawing a circle
    Received event. Shape area is now 49
    Drawing a rectangle
*/

```

How to implement interface events (C# Programming Guide)

12/28/2021 • 3 minutes to read • [Edit Online](#)

An [interface](#) can declare an [event](#). The following example shows how to implement interface events in a class. Basically the rules are the same as when you implement any interface method or property.

To implement interface events in a class

Declare the event in your class and then invoke it in the appropriate areas.

```
namespace ImplementInterfaceEvents
{
    public interface IDrawingObject
    {
        event EventHandler ShapeChanged;
    }
    public class MyEventArgs : EventArgs
    {
        // class members
    }
    public class Shape : IDrawingObject
    {
        public event EventHandler ShapeChanged;
        void ChangeShape()
        {
            // Do something here before the event...

            OnShapeChanged(new MyEventArgs(/*arguments*/));

            // or do something here after the event.
        }
        protected virtual void OnShapeChanged(MyEventArgs e)
        {
            ShapeChanged?.Invoke(this, e);
        }
    }
}
```

Example

The following example shows how to handle the less-common situation in which your class inherits from two or more interfaces and each interface has an event with the same name. In this situation, you must provide an explicit interface implementation for at least one of the events. When you write an explicit interface implementation for an event, you must also write the `add` and `remove` event accessors. Normally these are provided by the compiler, but in this case the compiler cannot provide them.

By providing your own accessors, you can specify whether the two events are represented by the same event in your class, or by different events. For example, if the events should be raised at different times according to the interface specifications, you can associate each event with a separate implementation in your class. In the following example, subscribers determine which `OnDraw` event they will receive by casting the shape reference to either an `IShape` or an `IDrawingObject`.

```

namespace WrapTwoInterfaceEvents
{
    using System;

    public interface IDrawingObject
    {
        // Raise this event before drawing
        // the object.
        event EventHandler OnDraw;
    }

    public interface IShape
    {
        // Raise this event after drawing
        // the shape.
        event EventHandler OnDraw;
    }

    // Base class event publisher inherits two
    // interfaces, each with an OnDraw event
    public class Shape : IDrawingObject, IShape
    {
        // Create an event for each interface event
        event EventHandler PreDrawEvent;
        event EventHandler PostDrawEvent;

        object objectLock = new Object();

        // Explicit interface implementation required.
        // Associate IDrawingObject's event with
        // PreDrawEvent
        #region IDrawingObjectOnDraw
        event EventHandler IDrawingObject.OnDraw
        {
            add
            {
                lock (objectLock)
                {
                    PreDrawEvent += value;
                }
            }
            remove
            {
                lock (objectLock)
                {
                    PreDrawEvent -= value;
                }
            }
        }
        #endregion
        // Explicit interface implementation required.
        // Associate IShape's event with
        // PostDrawEvent
        event EventHandler IShape.OnDraw
        {
            add
            {
                lock (objectLock)
                {
                    PostDrawEvent += value;
                }
            }
            remove
            {
                lock (objectLock)
                {
                    PostDrawEvent -= value;
                }
            }
        }
    }
}

```

```

// For the sake of simplicity this one method
// implements both interfaces.
public void Draw()
{
    // Raise IDrawingObject's event before the object is drawn.
    PreDrawEvent?.Invoke(this, EventArgs.Empty);

    Console.WriteLine("Drawing a shape.");

    // Raise IShape's event after the object is drawn.
    PostDrawEvent?.Invoke(this, EventArgs.Empty);
}
}
public class Subscriber1
{
    // References the shape object as an IDrawingObject
    public Subscriber1(Shape shape)
    {
        IDrawingObject d = (IDrawingObject)shape;
        d.OnDraw += d_OnDraw;
    }

    void d_OnDraw(object sender, EventArgs e)
    {
        Console.WriteLine("Sub1 receives the IDrawingObject event.");
    }
}
// References the shape object as an IShape
public class Subscriber2
{
    public Subscriber2(Shape shape)
    {
        IShape d = (IShape)shape;
        d.OnDraw += d_OnDraw;
    }

    void d_OnDraw(object sender, EventArgs e)
    {
        Console.WriteLine("Sub2 receives the IShape event.");
    }
}

public class Program
{
    static void Main(string[] args)
    {
        Shape shape = new Shape();
        Subscriber1 sub = new Subscriber1(shape);
        Subscriber2 sub2 = new Subscriber2(shape);
        shape.Draw();

        // Keep the console window open in debug mode.
        System.Console.WriteLine("Press any key to exit.");
        System.Console.ReadKey();
    }
}
}
/* Output:
Sub1 receives the IDrawingObject event.
Drawing a shape.
Sub2 receives the IShape event.
*/

```

How to implement custom event accessors (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

An event is a special kind of multicast delegate that can only be invoked from within the class that it is declared in. Client code subscribes to the event by providing a reference to a method that should be invoked when the event is fired. These methods are added to the delegate's invocation list through event accessors, which resemble property accessors, except that event accessors are named `add` and `remove`. In most cases, you do not have to supply custom event accessors. When no custom event accessors are supplied in your code, the compiler will add them automatically. However, in some cases you may have to provide custom behavior. One such case is shown in the topic [How to implement interface events](#).

Example

The following example shows how to implement custom add and remove event accessors. Although you can substitute any code inside the accessors, we recommend that you lock the event before you add or remove a new event handler method.

```
event EventHandler IDrawingObject.OnDraw
{
    add
    {
        lock (objectLock)
        {
            PreDrawEvent += value;
        }
    }
    remove
    {
        lock (objectLock)
        {
            PreDrawEvent -= value;
        }
    }
}
```

Generic type parameters (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

In a generic type or method definition, a type parameter is a placeholder for a specific type that a client specifies when they create an instance of the generic type. A generic class, such as `GenericList<T>` listed in [Introduction to Generics](#), cannot be used as-is because it is not really a type; it is more like a blueprint for a type. To use `GenericList<T>`, client code must declare and instantiate a constructed type by specifying a type argument inside the angle brackets. The type argument for this particular class can be any type recognized by the compiler. Any number of constructed type instances can be created, each one using a different type argument, as follows:

```
GenericList<float> list1 = new GenericList<float>();
GenericList<ExampleClass> list2 = new GenericList<ExampleClass>();
GenericList<ExampleStruct> list3 = new GenericList<ExampleStruct>();
```

In each of these instances of `GenericList<T>`, every occurrence of `T` in the class is substituted at run time with the type argument. By means of this substitution, we have created three separate type-safe and efficient objects using a single class definition. For more information on how this substitution is performed by the CLR, see [Generics in the Run Time](#).

Type parameter naming guidelines

- **Do** name generic type parameters with descriptive names, unless a single letter name is completely self explanatory and a descriptive name would not add value.

```
public interface ISessionChannel<TSession> { /*...*/ }
public delegate TOutput Converter<TInput, TOutput>(TInput from);
public class List<T> { /*...*/ }
```

- **Consider** using `T` as the type parameter name for types with one single letter type parameter.

```
public int IComparer<T>() { return 0; }
public delegate bool Predicate<T>(T item);
public struct Nullable<T> where T : struct { /*...*/ }
```

- **Do** prefix descriptive type parameter names with "T".

```
public interface ISessionChannel<TSession>
{
    TSession Session { get; }
}
```

- **Consider** indicating constraints placed on a type parameter in the name of parameter. For example, a parameter constrained to `ISession` may be called `TSession`.

The code analysis rule [CA1715](#) can be used to ensure that type parameters are named appropriately.

Constraints on type parameters (C# Programming Guide)

12/28/2021 • 11 minutes to read • [Edit Online](#)

Constraints inform the compiler about the capabilities a type argument must have. Without any constraints, the type argument could be any type. The compiler can only assume the members of [System.Object](#), which is the ultimate base class for any .NET type. For more information, see [Why use constraints](#). If client code uses a type that doesn't satisfy a constraint, the compiler issues an error. Constraints are specified by using the `where` contextual keyword. The following table lists the various types of constraints:

CONSTRAINT	DESCRIPTION
<code>where T : struct</code>	The type argument must be a non-nullable value type . For information about nullable value types, see Nullable value types . Because all value types have an accessible parameterless constructor, the <code>struct</code> constraint implies the <code>new()</code> constraint and can't be combined with the <code>new()</code> constraint. You can't combine the <code>struct</code> constraint with the <code>unmanaged</code> constraint.
<code>where T : class</code>	The type argument must be a reference type. This constraint applies also to any class, interface, delegate, or array type. In a nullable context in C# 8.0 or later, <code>T</code> must be a non-nullable reference type.
<code>where T : class?</code>	The type argument must be a reference type, either nullable or non-nullable. This constraint applies also to any class, interface, delegate, or array type.
<code>where T : notnull</code>	The type argument must be a non-nullable type. The argument can be a non-nullable reference type in C# 8.0 or later, or a non-nullable value type.
<code>where T : default</code>	This constraint resolves the ambiguity when you need to specify an unconstrained type parameter when you override a method or provide an explicit interface implementation. The <code>default</code> constraint implies the base method without either the <code>class</code> or <code>struct</code> constraint. For more information, see the default constraint spec proposal.
<code>where T : unmanaged</code>	The type argument must be a non-nullable unmanaged type . The <code>unmanaged</code> constraint implies the <code>struct</code> constraint and can't be combined with either the <code>struct</code> or <code>new()</code> constraints.
<code>where T : new()</code>	The type argument must have a public parameterless constructor. When used together with other constraints, the <code>new()</code> constraint must be specified last. The <code>new()</code> constraint can't be combined with the <code>struct</code> and <code>unmanaged</code> constraints.

CONSTRAINT	DESCRIPTION
<code>where T : <base class name></code>	The type argument must be or derive from the specified base class. In a nullable context in C# 8.0 and later, <code>T</code> must be a non-nullable reference type derived from the specified base class.
<code>where T : <base class name>?</code>	The type argument must be or derive from the specified base class. In a nullable context in C# 8.0 and later, <code>T</code> may be either a nullable or non-nullable type derived from the specified base class.
<code>where T : <interface name></code>	The type argument must be or implement the specified interface. Multiple interface constraints can be specified. The constraining interface can also be generic. In a nullable context in C# 8.0 and later, <code>T</code> must be a non-nullable type that implements the specified interface.
<code>where T : <interface name>?</code>	The type argument must be or implement the specified interface. Multiple interface constraints can be specified. The constraining interface can also be generic. In a nullable context in C# 8.0, <code>T</code> may be a nullable reference type, a non-nullable reference type, or a value type. <code>T</code> may not be a nullable value type.
<code>where T : U</code>	The type argument supplied for <code>T</code> must be or derive from the argument supplied for <code>U</code> . In a nullable context, if <code>U</code> is a non-nullable reference type, <code>T</code> must be non-nullable reference type. If <code>U</code> is a nullable reference type, <code>T</code> may be either nullable or non-nullable.

Why use constraints

Constraints specify the capabilities and expectations of a type parameter. Declaring those constraints means you can use the operations and method calls of the constraining type. If your generic class or method uses any operation on the generic members beyond simple assignment or calling any methods not supported by [System.Object](#), you'll apply constraints to the type parameter. For example, the base class constraint tells the compiler that only objects of this type or derived from this type will be used as type arguments. Once the compiler has this guarantee, it can allow methods of that type to be called in the generic class. The following code example demonstrates the functionality you can add to the `GenericList<T>` class (in [Introduction to Generics](#)) by applying a base class constraint.

```

public class Employee
{
    public Employee(string name, int id) => (Name, ID) = (name, id);
    public string Name { get; set; }
    public int ID { get; set; }
}

public class GenericList<T> where T : Employee
{
    private class Node
    {
        public Node(T t) => (Next, Data) = (null, t);

        public Node Next { get; set; }
        public T Data { get; set; }
    }

    private Node head;

    public void AddHead(T t)
    {
        Node n = new Node(t) { Next = head };
        head = n;
    }

    public IEnumerator<T> GetEnumerator()
    {
        Node current = head;

        while (current != null)
        {
            yield return current.Data;
            current = current.Next;
        }
    }

    public T FindFirstOccurrence(string s)
    {
        Node current = head;
        T t = null;

        while (current != null)
        {
            //The constraint enables access to the Name property.
            if (current.Data.Name == s)
            {
                t = current.Data;
                break;
            }
            else
            {
                current = current.Next;
            }
        }
        return t;
    }
}

```

The constraint enables the generic class to use the `Employee.Name` property. The constraint specifies that all items of type `T` are guaranteed to be either an `Employee` object or an object that inherits from `Employee`.

Multiple constraints can be applied to the same type parameter, and the constraints themselves can be generic types, as follows:

```
class EmployeeList<T> where T : Employee, IEmployee, System.IComparable<T>, new()
{
    // ...
}
```

When applying the `where T : class` constraint, avoid the `==` and `!=` operators on the type parameter because these operators will test for reference identity only, not for value equality. This behavior occurs even if these operators are overloaded in a type that is used as an argument. The following code illustrates this point; the output is false even though the `String` class overloads the `==` operator.

```
public static void OpEqualsTest<T>(T s, T t) where T : class
{
    System.Console.WriteLine(s == t);
}

private static void TestStringEquality()
{
    string s1 = "target";
    System.Text.StringBuilder sb = new System.Text.StringBuilder("target");
    string s2 = sb.ToString();
    OpEqualsTest<string>(s1, s2);
}
```

The compiler only knows that `T` is a reference type at compile time and must use the default operators that are valid for all reference types. If you must test for value equality, the recommended way is to also apply the `where T : IEquatable<T>` or `where T : IComparable<T>` constraint and implement the interface in any class that will be used to construct the generic class.

Constraining multiple parameters

You can apply constraints to multiple parameters, and multiple constraints to a single parameter, as shown in the following example:

```
class Base { }
class Test<T, U>
    where U : struct
    where T : Base, new()
{ }
```

Unbounded type parameters

Type parameters that have no constraints, such as `T` in public class `SampleClass<T>{}`, are called unbounded type parameters. Unbounded type parameters have the following rules:

- The `!=` and `==` operators can't be used because there's no guarantee that the concrete type argument will support these operators.
- They can be converted to and from `System.Object` or explicitly converted to any interface type.
- You can compare them to `null`. If an unbounded parameter is compared to `null`, the comparison will always return false if the type argument is a value type.

Type parameters as constraints

The use of a generic type parameter as a constraint is useful when a member function with its own type parameter has to constrain that parameter to the type parameter of the containing type, as shown in the following example:

```
public class List<T>
{
    public void Add<U>(List<U> items) where U : T { /*...*/ }
}
```

In the previous example, `T` is a type constraint in the context of the `Add` method, and an unbounded type parameter in the context of the `List` class.

Type parameters can also be used as constraints in generic class definitions. The type parameter must be declared within the angle brackets together with any other type parameters:

```
//Type parameter V is used as a type constraint.
public class SampleClass<T, U, V> where T : V { }
```

The usefulness of type parameters as constraints with generic classes is limited because the compiler can assume nothing about the type parameter except that it derives from `System.Object`. Use type parameters as constraints on generic classes in scenarios in which you want to enforce an inheritance relationship between two type parameters.

nonnull constraint

Beginning with C# 8.0, you can use the `nonnull` constraint to specify that the type argument must be a non-nullable value type or non-nullable reference type. Unlike most other constraints, if a type argument violates the `nonnull` constraint, the compiler generates a warning instead of an error.

The `nonnull` constraint has an effect only when used in a nullable context. If you add the `nonnull` constraint in a nullable oblivious context, the compiler doesn't generate any warnings or errors for violations of the constraint.

class constraint

Beginning with C# 8.0, the `class` constraint in a nullable context specifies that the type argument must be a non-nullable reference type. In a nullable context, when a type argument is a nullable reference type, the compiler generates a warning.

default constraint

The addition of nullable reference types complicates the use of `T?` in a generic type or method. Prior to C# 8, `T?` could only be used when the `struct` constraint applied to `T`. In that context, `T?` refers to the `Nullable<T>` type for `T`. Starting with C# 8, `T?` could be used with either the `struct` or `class` constraint, but one of them must be present. When the `class` constraint was used, `T?` referred to the nullable reference type for `T`. Beginning with C# 9, `T?` can be used when neither constraint is applied. In that case, `T?` is interpreted the same as in C# 8 for value types and reference types. However, if `T` is an instance of `Nullable<T>`, `T?` is the same as `T`. In other words, it doesn't become `T??`.

Because `T?` can now be used without either the `class` or `struct` constraint, ambiguities can arise in overrides or explicit interface implementations. In both those cases, the override doesn't include the constraints, but inherits them from the base class. When the base class doesn't apply either the `class` or `struct` constraint, derived classes need to somehow specify an override applies to the base method without either constraint. That's when the derived method applies the `default` constraint. The `default` constraint clarifies *neither* the `class` nor `struct` constraint.

Unmanaged constraint

Beginning with C# 7.3, you can use the `unmanaged` constraint to specify that the type parameter must be a non-nullable [unmanaged type](#). The `unmanaged` constraint enables you to write reusable routines to work with types that can be manipulated as blocks of memory, as shown in the following example:

```
unsafe public static byte[] ToByteArray<T>(this T argument) where T : unmanaged
{
    var size = sizeof(T);
    var result = new Byte[size];
    Byte* p = (byte*)&argument;
    for (var i = 0; i < size; i++)
        result[i] = *p++;
    return result;
}
```

The preceding method must be compiled in an `unsafe` context because it uses the `sizeof` operator on a type not known to be a built-in type. Without the `unmanaged` constraint, the `sizeof` operator is unavailable.

The `unmanaged` constraint implies the `struct` constraint and can't be combined with it. Because the `struct` constraint implies the `new()` constraint, the `unmanaged` constraint can't be combined with the `new()` constraint as well.

Delegate constraints

Also beginning with C# 7.3, you can use [System.Delegate](#) or [System.MulticastDelegate](#) as a base class constraint. The CLR always allowed this constraint, but the C# language disallowed it. The `System.Delegate` constraint enables you to write code that works with delegates in a type-safe manner. The following code defines an extension method that combines two delegates provided they're the same type:

```
public static TDelegate TypeSafeCombine<TDelegate>(this TDelegate source, TDelegate target)
    where TDelegate : System.Delegate
    => Delegate.Combine(source, target) as TDelegate;
```

You can use the above method to combine delegates that are the same type:

```
Action first = () => Console.WriteLine("this");
Action second = () => Console.WriteLine("that");

var combined = first.TypeSafeCombine(second);
combined();

Func<bool> test = () => true;
// Combine signature ensures combined delegates must
// have the same type.
//var badCombined = first.TypeSafeCombine(test);
```

If you uncomment the last line, it won't compile. Both `first` and `test` are delegate types, but they're different delegate types.

Enum constraints

Beginning in C# 7.3, you can also specify the [System.Enum](#) type as a base class constraint. The CLR always allowed this constraint, but the C# language disallowed it. Generics using `System.Enum` provide type-safe programming to cache results from using the static methods in `System.Enum`. The following sample finds all the valid values for an enum type, and then builds a dictionary that maps those values to its string representation.

```
public static Dictionary<int, string> EnumNamedValues<T>() where T : System.Enum
{
    var result = new Dictionary<int, string>();
    var values = Enum.GetValues(typeof(T));

    foreach (int item in values)
        result.Add(item, Enum.GetName(typeof(T), item));
    return result;
}
```

`Enum.GetValues` and `Enum.GetName` use reflection, which has performance implications. You can call `EnumNamedValues` to build a collection that is cached and reused rather than repeating the calls that require reflection.

You could use it as shown in the following sample to create an enum and build a dictionary of its values and names:

```
enum Rainbow
{
    Red,
    Orange,
    Yellow,
    Green,
    Blue,
    Indigo,
    Violet
}
```

```
var map = EnumNamedValues<Rainbow>();

foreach (var pair in map)
    Console.WriteLine($"{pair.Key}: \t{pair.Value}");
```

Generic Classes (C# Programming Guide)

12/28/2021 • 3 minutes to read • [Edit Online](#)

Generic classes encapsulate operations that are not specific to a particular data type. The most common use for generic classes is with collections like linked lists, hash tables, stacks, queues, trees, and so on. Operations such as adding and removing items from the collection are performed in basically the same way regardless of the type of data being stored.

For most scenarios that require collection classes, the recommended approach is to use the ones provided in the .NET class library. For more information about using these classes, see [Generic Collections in .NET](#).

Typically, you create generic classes by starting with an existing concrete class, and changing types into type parameters one at a time until you reach the optimal balance of generalization and usability. When creating your own generic classes, important considerations include the following:

- Which types to generalize into type parameters.

As a rule, the more types you can parameterize, the more flexible and reusable your code becomes. However, too much generalization can create code that is difficult for other developers to read or understand.

- What constraints, if any, to apply to the type parameters (See [Constraints on Type Parameters](#)).

A good rule is to apply the maximum constraints possible that will still let you handle the types you must handle. For example, if you know that your generic class is intended for use only with reference types, apply the class constraint. That will prevent unintended use of your class with value types, and will enable you to use the `as` operator on `T`, and check for null values.

- Whether to factor generic behavior into base classes and subclasses.

Because generic classes can serve as base classes, the same design considerations apply here as with non-generic classes. See the rules about inheriting from generic base classes later in this topic.

- Whether to implement one or more generic interfaces.

For example, if you are designing a class that will be used to create items in a generics-based collection, you may have to implement an interface such as `Comparable<T>` where `T` is the type of your class.

For an example of a simple generic class, see [Introduction to Generics](#).

The rules for type parameters and constraints have several implications for generic class behavior, especially regarding inheritance and member accessibility. Before proceeding, you should understand some terms. For a generic class `Node<T>`, client code can reference the class either by specifying a type argument, to create a closed constructed type (`Node<int>`). Alternatively, it can leave the type parameter unspecified, for example when you specify a generic base class, to create an open constructed type (`Node<T>`). Generic classes can inherit from concrete, closed constructed, or open constructed base classes:

```

class BaseNode { }
class BaseNodeGeneric<T> { }

// concrete type
class NodeConcrete<T> : BaseNode { }

//closed constructed type
class NodeClosed<T> : BaseNodeGeneric<int> { }

//open constructed type
class NodeOpen<T> : BaseNodeGeneric<T> { }

```

Non-generic, in other words, concrete, classes can inherit from closed constructed base classes, but not from open constructed classes or from type parameters because there is no way at run time for client code to supply the type argument required to instantiate the base class.

```

//No error
class Node1 : BaseNodeGeneric<int> { }

//Generates an error
//class Node2 : BaseNodeGeneric<T> {}

//Generates an error
//class Node3 : T {}

```

Generic classes that inherit from open constructed types must supply type arguments for any base class type parameters that are not shared by the inheriting class, as demonstrated in the following code:

```

class BaseNodeMultiple<T, U> { }

//No error
class Node4<T> : BaseNodeMultiple<T, int> { }

//No error
class Node5<T, U> : BaseNodeMultiple<T, U> { }

//Generates an error
//class Node6<T> : BaseNodeMultiple<T, U> {}

```

Generic classes that inherit from open constructed types must specify constraints that are a superset of, or imply, the constraints on the base type:

```

class NodeItem<T> where T : System.IComparable<T>, new() { }
class SpecialNodeItem<T> : NodeItem<T> where T : System.IComparable<T>, new() { }

```

Generic types can use multiple type parameters and constraints, as follows:

```

class SuperKeyType<K, V, U>
    where U : System.IComparable<U>
    where V : new()
{ }

```

Open constructed and closed constructed types can be used as method parameters:

```
void Swap<T>(List<T> list1, List<T> list2)
{
    //code to swap items
}

void Swap(List<int> list1, List<int> list2)
{
    //code to swap items
}
```

If a generic class implements an interface, all instances of that class can be cast to that interface.

Generic classes are invariant. In other words, if an input parameter specifies a `List<BaseClass>`, you will get a compile-time error if you try to provide a `List<DerivedClass>`.

Generic Interfaces (C# Programming Guide)

12/28/2021 • 4 minutes to read • [Edit Online](#)

It is often useful to define interfaces either for generic collection classes, or for the generic classes that represent items in the collection. The preference for generic classes is to use generic interfaces, such as [IComparable<T>](#) rather than [IComparable](#), in order to avoid boxing and unboxing operations on value types. The .NET class library defines several generic interfaces for use with the collection classes in the [System.Collections.Generic](#) namespace.

When an interface is specified as a constraint on a type parameter, only types that implement the interface can be used. The following code example shows a `SortedList<T>` class that derives from the `GenericList<T>` class. For more information, see [Introduction to Generics](#). `SortedList<T>` adds the constraint `where T : IComparable<T>`. This enables the `BubbleSort` method in `SortedList<T>` to use the generic [CompareTo](#) method on list elements. In this example, list elements are a simple class, `Person`, that implements `IComparable<Person>`.

```
//Type parameter T in angle brackets.
public class GenericList<T> : System.Collections.Generic.IEnumerable<T>
{
    protected Node head;
    protected Node current = null;

    // Nested class is also generic on T
    protected class Node
    {
        public Node next;
        private T data; //T as private member datatype

        public Node(T t) //T used in non-generic constructor
        {
            next = null;
            data = t;
        }

        public Node Next
        {
            get { return next; }
            set { next = value; }
        }

        public T Data //T as return type of property
        {
            get { return data; }
            set { data = value; }
        }
    }

    public GenericList() //constructor
    {
        head = null;
    }

    public void AddHead(T t) //T as method parameter type
    {
        Node n = new Node(t);
        n.Next = head;
        head = n;
    }
}
```

```

// Implementation of the iterator
public System.Collections.Generic.IEnumerator<T> GetEnumerator()
{
    Node current = head;
    while (current != null)
    {
        yield return current.Data;
        current = current.Next;
    }
}

// IEnumerable<T> inherits from IEnumerable, therefore this class
// must implement both the generic and non-generic versions of
// GetEnumerator. In most cases, the non-generic method can
// simply call the generic method.
System.Collections.IEnumerator System.Collections.IEnumerable.GetEnumerator()
{
    return GetEnumerator();
}
}

public class SortedList<T> : GenericList<T> where T : System.IComparable<T>
{
    // A simple, unoptimized sort algorithm that
    // orders list elements from lowest to highest:

    public void BubbleSort()
    {
        if (null == head || null == head.Next)
        {
            return;
        }
        bool swapped;

        do
        {
            Node previous = null;
            Node current = head;
            swapped = false;

            while (current.next != null)
            {
                // Because we need to call this method, the SortedList
                // class is constrained on IComparable<T>
                if (current.Data.CompareTo(current.next.Data) > 0)
                {
                    Node tmp = current.next;
                    current.next = current.next.next;
                    tmp.next = current;

                    if (previous == null)
                    {
                        head = tmp;
                    }
                    else
                    {
                        previous.next = tmp;
                    }
                    previous = tmp;
                    swapped = true;
                }
                else
                {
                    previous = current;
                    current = current.next;
                }
            }
        } while (swapped);
    }
}

```

```

}

// A simple class that implements IComparable<T> using itself as the
// type argument. This is a common design pattern in objects that
// are stored in generic lists.
public class Person : System.IComparable<Person>
{
    string name;
    int age;

    public Person(string s, int i)
    {
        name = s;
        age = i;
    }

    // This will cause list elements to be sorted on age values.
    public int CompareTo(Person p)
    {
        return age - p.age;
    }

    public override string ToString()
    {
        return name + ":" + age;
    }

    // Must implement Equals.
    public bool Equals(Person p)
    {
        return (this.age == p.age);
    }
}

public class Program
{
    public static void Main()
    {
        //Declare and instantiate a new generic SortedList class.
        //Person is the type argument.
        SortedList<Person> list = new SortedList<Person>();

        //Create name and age values to initialize Person objects.
        string[] names = new string[]
        {
            "Franscoise",
            "Bill",
            "Li",
            "Sandra",
            "Gunnar",
            "Alok",
            "Hiroyuki",
            "Maria",
            "Alessandro",
            "Raul"
        };

        int[] ages = new int[] { 45, 19, 28, 23, 18, 9, 108, 72, 30, 35 };

        //Populate the list.
        for (int x = 0; x < 10; x++)
        {
            list.AddHead(new Person(names[x], ages[x]));
        }

        //Print out unsorted list.
        foreach (Person p in list)
        {
            System.Console.WriteLine(p.ToString());
        }
    }
}

```

```

    }
    System.Console.WriteLine("Done with unsorted list");

    //Sort the list.
    list.BubbleSort();

    //Print out sorted list.
    foreach (Person p in list)
    {
        System.Console.WriteLine(p.ToString());
    }
    System.Console.WriteLine("Done with sorted list");
}
}

```

Multiple interfaces can be specified as constraints on a single type, as follows:

```

class Stack<T> where T : System.IComparable<T>, IEnumerable<T>
{
}

```

An interface can define more than one type parameter, as follows:

```

interface IDictionary<K, V>
{
}

```

The rules of inheritance that apply to classes also apply to interfaces:

```

interface IMonth<T> { }

interface IJanuary    : IMonth<int> { } //No error
interface IFebruary<T> : IMonth<int> { } //No error
interface IMarch<T>    : IMonth<T> { }   //No error
//interface IApril<T>   : IMonth<T, U> { } //Error

```

Generic interfaces can inherit from non-generic interfaces if the generic interface is covariant, which means it only uses its type parameter as a return value. In the .NET class library, [IEnumerable<T>](#) inherits from [IEnumerable](#) because [IEnumerable<T>](#) only uses [T](#) in the return value of [GetEnumerator](#) and in the [Current](#) property getter.

Concrete classes can implement closed constructed interfaces, as follows:

```

interface IBaseInterface<T> { }

class SampleClass : IBaseInterface<string> { }

```

Generic classes can implement generic interfaces or closed constructed interfaces as long as the class parameter list supplies all arguments required by the interface, as follows:

```

interface IBaseInterface1<T> { }
interface IBaseInterface2<T, U> { }

class SampleClass1<T> : IBaseInterface1<T> { } //No error
class SampleClass2<T> : IBaseInterface2<T, string> { } //No error

```

The rules that control method overloading are the same for methods within generic classes, generic structs, or

generic interfaces. For more information, see [Generic Methods](#).

Generic Methods (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

A generic method is a method that is declared with type parameters, as follows:

```
static void Swap<T>(ref T lhs, ref T rhs)
{
    T temp;
    temp = lhs;
    lhs = rhs;
    rhs = temp;
}
```

The following code example shows one way to call the method by using `int` for the type argument:

```
public static void TestSwap()
{
    int a = 1;
    int b = 2;

    Swap<int>(ref a, ref b);
    System.Console.WriteLine(a + " " + b);
}
```

You can also omit the type argument and the compiler will infer it. The following call to `Swap` is equivalent to the previous call:

```
Swap(ref a, ref b);
```

The same rules for type inference apply to static methods and instance methods. The compiler can infer the type parameters based on the method arguments you pass in; it cannot infer the type parameters only from a constraint or return value. Therefore type inference does not work with methods that have no parameters. Type inference occurs at compile time before the compiler tries to resolve overloaded method signatures. The compiler applies type inference logic to all generic methods that share the same name. In the overload resolution step, the compiler includes only those generic methods on which type inference succeeded.

Within a generic class, non-generic methods can access the class-level type parameters, as follows:

```
class SampleClass<T>
{
    void Swap(ref T lhs, ref T rhs) { }
}
```

If you define a generic method that takes the same type parameters as the containing class, the compiler generates warning [CS0693](#) because within the method scope, the argument supplied for the inner `T` hides the argument supplied for the outer `T`. If you require the flexibility of calling a generic class method with type arguments other than the ones provided when the class was instantiated, consider providing another identifier for the type parameter of the method, as shown in `GenericList2<T>` in the following example.

```

class GenericList<T>
{
    // CS0693
    void SampleMethod<T>() { }
}

class GenericList2<T>
{
    //No warning
    void SampleMethod<U>() { }
}

```

Use constraints to enable more specialized operations on type parameters in methods. This version of `Swap<T>`, now named `SwapIfGreater<T>`, can only be used with type arguments that implement [IComparable<T>](#).

```

void SwapIfGreater<T>(ref T lhs, ref T rhs) where T : System.IComparable<T>
{
    T temp;
    if (lhs.CompareTo(rhs) > 0)
    {
        temp = lhs;
        lhs = rhs;
        rhs = temp;
    }
}

```

Generic methods can be overloaded on several type parameters. For example, the following methods can all be located in the same class:

```

void DoWork() { }
void DoWork<T>() { }
void DoWork<T, U>() { }

```

Generics and Arrays (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

In C# 2.0 and later, single-dimensional arrays that have a lower bound of zero automatically implement [IList<T>](#). This enables you to create generic methods that can use the same code to iterate through arrays and other collection types. This technique is primarily useful for reading data in collections. The [IList<T>](#) interface cannot be used to add or remove elements from an array. An exception will be thrown if you try to call an [IList<T>](#) method such as [RemoveAt](#) on an array in this context.

The following code example demonstrates how a single generic method that takes an [IList<T>](#) input parameter can iterate through both a list and an array, in this case an array of integers.

```
class Program
{
    static void Main()
    {
        int[] arr = { 0, 1, 2, 3, 4 };
        List<int> list = new List<int>();

        for (int x = 5; x < 10; x++)
        {
            list.Add(x);
        }

        ProcessItems<int>(arr);
        ProcessItems<int>(list);
    }

    static void ProcessItems<T>(IList<T> coll)
    {
        // IsReadOnly returns True for the array and False for the List.
        System.Console.WriteLine
            ("IsReadOnly returns {0} for this collection.",
            coll.IsReadOnly);

        // The following statement causes a run-time exception for the
        // array, but not for the List.
        //coll.RemoveAt(4);

        foreach (T item in coll)
        {
            System.Console.Write(item.ToString() + " ");
        }
        System.Console.WriteLine();
    }
}
```

Generic Delegates (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

A [delegate](#) can define its own type parameters. Code that references the generic delegate can specify the type argument to create a closed constructed type, just like when instantiating a generic class or calling a generic method, as shown in the following example:

```
public delegate void Del<T>(T item);
public static void Notify(int i) { }

Del<int> m1 = new Del<int>(Notify);
```

C# version 2.0 has a new feature called method group conversion, which applies to concrete as well as generic delegate types, and enables you to write the previous line with this simplified syntax:

```
Del<int> m2 = Notify;
```

Delegates defined within a generic class can use the generic class type parameters in the same way that class methods do.

```
class Stack<T>
{
    T[] items;
    int index;

    public delegate void StackDelegate(T[] items);
}
```

Code that references the delegate must specify the type argument of the containing class, as follows:

```
private static void DoWork(float[] items) { }

public static void TestStack()
{
    Stack<float> s = new Stack<float>();
    Stack<float>.StackDelegate d = DoWork;
}
```

Generic delegates are especially useful in defining events based on the typical design pattern because the sender argument can be strongly typed and no longer has to be cast to and from [Object](#).

```

delegate void StackEventHandler<T, U>(T sender, U eventArgs);

class Stack<T>
{
    public class StackEventArgs : System.EventArgs { }
    public event StackEventHandler<Stack<T>, StackEventArgs> stackEvent;

    protected virtual void OnStackChanged(StackEventArgs a)
    {
        stackEvent(this, a);
    }
}

class SampleClass
{
    public void HandleStackChange<T>(Stack<T> stack, Stack<T>.StackEventArgs args) { }
}

public static void Test()
{
    Stack<double> s = new Stack<double>();
    SampleClass o = new SampleClass();
    s.stackEvent += o.HandleStackChange;
}

```

Differences Between C++ Templates and C# Generics (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

C# Generics and C++ templates are both language features that provide support for parameterized types. However, there are many differences between the two. At the syntax level, C# generics are a simpler approach to parameterized types without the complexity of C++ templates. In addition, C# does not attempt to provide all of the functionality that C++ templates provide. At the implementation level, the primary difference is that C# generic type substitutions are performed at run time and generic type information is thereby preserved for instantiated objects. For more information, see [Generics in the Run Time](#).

The following are the key differences between C# Generics and C++ templates:

- C# generics do not provide the same amount of flexibility as C++ templates. For example, it is not possible to call arithmetic operators in a C# generic class, although it is possible to call user defined operators.
- C# does not allow non-type template parameters, such as `template C<int i> {}`.
- C# does not support explicit specialization; that is, a custom implementation of a template for a specific type.
- C# does not support partial specialization: a custom implementation for a subset of the type arguments.
- C# does not allow the type parameter to be used as the base class for the generic type.
- C# does not allow type parameters to have default types.
- In C#, a generic type parameter cannot itself be a generic, although constructed types can be used as generics. C++ does allow template parameters.
- C++ allows code that might not be valid for all type parameters in the template, which is then checked for the specific type used as the type parameter. C# requires code in a class to be written in such a way that it will work with any type that satisfies the constraints. For example, in C++ it is possible to write a function that uses the arithmetic operators `+` and `-` on objects of the type parameter, which will produce an error at the time of instantiation of the template with a type that does not support these operators. C# disallows this; the only language constructs allowed are those that can be deduced from the constraints.

Generics in the Run Time (C# Programming Guide)

12/28/2021 • 3 minutes to read • [Edit Online](#)

When a generic type or method is compiled into Microsoft intermediate language (MSIL), it contains metadata that identifies it as having type parameters. How the MSIL for a generic type is used differs based on whether the supplied type parameter is a value type or reference type.

When a generic type is first constructed with a value type as a parameter, the runtime creates a specialized generic type with the supplied parameter or parameters substituted in the appropriate locations in the MSIL. Specialized generic types are created one time for each unique value type that is used as a parameter.

For example, suppose your program code declared a stack that is constructed of integers:

```
Stack<int> stack;
```

At this point, the runtime generates a specialized version of the `Stack<T>` class that has the integer substituted appropriately for its parameter. Now, whenever your program code uses a stack of integers, the runtime reuses the generated specialized `Stack<T>` class. In the following example, two instances of a stack of integers are created, and they share a single instance of the `Stack<int>` code:

```
Stack<int> stackOne = new Stack<int>();  
Stack<int> stackTwo = new Stack<int>();
```

However, suppose that another `Stack<T>` class with a different value type such as a `long` or a user-defined structure as its parameter is created at another point in your code. As a result, the runtime generates another version of the generic type and substitutes a `long` in the appropriate locations in MSIL. Conversions are no longer necessary because each specialized generic class natively contains the value type.

Generics work somewhat differently for reference types. The first time a generic type is constructed with any reference type, the runtime creates a specialized generic type with object references substituted for the parameters in the MSIL. Then, every time that a constructed type is instantiated with a reference type as its parameter, regardless of what type it is, the runtime reuses the previously created specialized version of the generic type. This is possible because all references are the same size.

For example, suppose you had two reference types, a `Customer` class and an `Order` class, and also suppose that you created a stack of `Customer` types:

```
class Customer { }  
class Order { }
```

```
Stack<Customer> customers;
```

At this point, the runtime generates a specialized version of the `Stack<T>` class that stores object references that will be filled in later instead of storing data. Suppose the next line of code creates a stack of another reference type, which is named `Order`:

```
Stack<Order> orders = new Stack<Order>();
```

Unlike with value types, another specialized version of the [Stack<T>](#) class is not created for the `Order` type. Instead, an instance of the specialized version of the [Stack<T>](#) class is created and the `orders` variable is set to reference it. Suppose that you then encountered a line of code to create a stack of a `Customer` type:

```
customers = new Stack<Customer>();
```

As with the previous use of the [Stack<T>](#) class created by using the `Order` type, another instance of the specialized [Stack<T>](#) class is created. The pointers that are contained therein are set to reference an area of memory the size of a `Customer` type. Because the number of reference types can vary wildly from program to program, the C# implementation of generics greatly reduces the amount of code by reducing to one the number of specialized classes created by the compiler for generic classes of reference types.

Moreover, when a generic C# class is instantiated by using a value type or reference type parameter, reflection can query it at run time and both its actual type and its type parameter can be ascertained.

Generics and Reflection (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Because the Common Language Runtime (CLR) has access to generic type information at run time, you can use reflection to obtain information about generic types in the same way as for non-generic types. For more information, see [Generics in the Run Time](#).

In .NET Framework 2.0, several new members were added to the [Type](#) class to enable run-time information for generic types. See the documentation on these classes for more information on how to use these methods and properties. The [System.Reflection.Emit](#) namespace also contains new members that support generics. See [How to: Define a Generic Type with Reflection Emit](#).

For a list of the invariant conditions for terms used in generic reflection, see the [IsGenericType](#) property remarks.

SYSTEM.TYPE MEMBER NAME	DESCRIPTION
IsGenericType	Returns true if a type is generic.
GetGenericArguments	Returns an array of Type objects that represent the type arguments supplied for a constructed type, or the type parameters of a generic type definition.
GetGenericTypeDefinition	Returns the underlying generic type definition for the current constructed type.
GetGenericParameterConstraints	Returns an array of Type objects that represent the constraints on the current generic type parameter.
ContainsGenericParameters	Returns true if the type or any of its enclosing types or methods contain type parameters for which specific types have not been supplied.
GenericParameterAttributes	Gets a combination of GenericParameterAttributes flags that describe the special constraints of the current generic type parameter.
GenericParameterPosition	For a Type object that represents a type parameter, gets the position of the type parameter in the type parameter list of the generic type definition or generic method definition that declared the type parameter.
IsGenericParameter	Gets a value that indicates whether the current Type represents a type parameter of a generic type or method definition.
IsGenericTypeDefinition	Gets a value that indicates whether the current Type represents a generic type definition, from which other generic types can be constructed. Returns true if the type represents the definition of a generic type.

SYSTEM.TYPE MEMBER NAME	DESCRIPTION
DeclaringMethod	Returns the generic method that defined the current generic type parameter, or null if the type parameter was not defined by a generic method.
MakeGenericType	Substitutes the elements of an array of types for the type parameters of the current generic type definition, and returns a Type object representing the resulting constructed type.

In addition, members of the [MethodInfo](#) class enable run-time information for generic methods. See the [IsGenericMethod](#) property remarks for a list of invariant conditions for terms used to reflect on generic methods.

SYSTEM.REFLECTION.MEMBERINFO MEMBER NAME	DESCRIPTION
IsGenericMethod	Returns true if a method is generic.
GetGenericArguments	Returns an array of Type objects that represent the type arguments of a constructed generic method or the type parameters of a generic method definition.
GetGenericMethodDefinition	Returns the underlying generic method definition for the current constructed method.
ContainsGenericParameters	Returns true if the method or any of its enclosing types contain any type parameters for which specific types have not been supplied.
IsGenericMethodDefinition	Returns true if the current MethodInfo represents the definition of a generic method.
MakeGenericMethod	Substitutes the elements of an array of types for the type parameters of the current generic method definition, and returns a MethodInfo object representing the resulting constructed method.

Generics and Attributes (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Attributes can be applied to generic types in the same way as non-generic types. For more information on applying attributes, see [Attributes](#).

Custom attributes are only permitted to reference open generic types, which are generic types for which no type arguments are supplied, and closed constructed generic types, which supply arguments for all type parameters.

The following examples use this custom attribute:

```
class CustomAttribute : System.Attribute
{
    public System.Object info;
}
```

An attribute can reference an open generic type:

```
public class GenericClass1<T> { }

[CustomAttribute(info = typeof(GenericClass1<>))]
class ClassA { }
```

Specify multiple type parameters using the appropriate number of commas. In this example, `GenericClass2` has two type parameters:

```
public class GenericClass2<T, U> { }

[CustomAttribute(info = typeof(GenericClass2<,>))]
class ClassB { }
```

An attribute can reference a closed constructed generic type:

```
public class GenericClass3<T, U, V> { }

[CustomAttribute(info = typeof(GenericClass3<int, double, string>))]
class ClassC { }
```

An attribute that references a generic type parameter will cause a compile-time error:

```
//[CustomAttribute(info = typeof(GenericClass3<int, T, string>))] //Error
class ClassD<T> { }
```

A generic type cannot inherit from [Attribute](#):

```
//public class CustomAtt<T> : System.Attribute { } //Error
```

To obtain information about a generic type or type parameter at run time, you can use the methods of [System.Reflection](#). For more information, see [Generics and Reflection](#)

File system and the registry (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The following articles show how to use C# and .NET to perform various basic operations on files, folders, and the registry.

In this section

TITLE	DESCRIPTION
How to iterate through a directory tree	Shows how to manually iterate through a directory tree.
How to get information about files, folders, and drives	Shows how to retrieve information such as creation times and size, about files, folders and drives.
How to create a file or folder	Shows how to create a new file or folder.
How to copy, delete, and move files and folders (C# Programming Guide)	Shows how to copy, delete and move files and folders.
How to provide a progress dialog box for file operations	Shows how to display a standard Windows progress dialog for certain file operations.
How to write to a text file	Shows how to write to a text file.
How to read from a text file	Shows how to read from a text file.
How to read a text file one line at a time	Shows how to retrieve text from a file one line at a time.
How to create a key in the registry	Shows how to write a key to the system registry.

How to iterate through a directory tree (C# Programming Guide)

12/28/2021 • 7 minutes to read • [Edit Online](#)

The phrase "iterate a directory tree" means to access each file in each nested subdirectory under a specified root folder, to any depth. You do not necessarily have to open each file. You can just retrieve the name of the file or subdirectory as a `string`, or you can retrieve additional information in the form of a [System.IO.FileInfo](#) or [System.IO.DirectoryInfo](#) object.

NOTE

In Windows, the terms "directory" and "folder" are used interchangeably. Most documentation and user interface text uses the term "folder," but .NET class libraries use the term "directory."

In the simplest case, in which you know for certain that you have access permissions for all directories under a specified root, you can use the `System.IO.SearchOption.AllDirectories` flag. This flag returns all the nested subdirectories that match the specified pattern. The following example shows how to use this flag.

```
root.GetDirectories("*.**", System.IO.SearchOption.AllDirectories);
```

The weakness in this approach is that if any one of the subdirectories under the specified root causes a [DirectoryNotFoundException](#) or [UnauthorizedAccessException](#), the whole method fails and returns no directories. The same is true when you use the [GetFiles](#) method. If you have to handle these exceptions on specific subfolders, you must manually walk the directory tree, as shown in the following examples.

When you manually walk a directory tree, you can handle the files first (*pre-order traversal*), or the subdirectories first (*post-order traversal*). If you perform a pre-order traversal, you visit files directly under that folder itself, and then walk the whole tree under the current folder. Post-order traversal is the other way around, walking the whole tree beneath before getting to the current folder's files. The examples later in this document perform pre-order traversal, but you can easily modify them to perform post-order traversal.

Another option is whether to use recursion or a stack-based traversal. The examples later in this document show both approaches.

If you have to perform a variety of operations on files and folders, you can modularize these examples by refactoring the operation into separate functions that you can invoke by using a single delegate.

NOTE

NTFS file systems can contain *reparse points* in the form of *junction points*, *symbolic links*, and *hard links*. .NET methods such as [GetFiles](#) and [GetDirectories](#) will not return any subdirectories under a reparse point. This behavior guards against the risk of entering into an infinite loop when two reparse points refer to each other. In general, you should use extreme caution when you deal with reparse points to ensure that you do not unintentionally modify or delete files. If you require precise control over reparse points, use platform invoke or native code to call the appropriate Win32 file system methods directly.

Examples

The following example shows how to walk a directory tree by using recursion. The recursive approach is elegant but has the potential to cause a stack overflow exception if the directory tree is large and deeply nested.

The particular exceptions that are handled, and the particular actions that are performed on each file or folder, are provided as examples only. You should modify this code to meet your specific requirements. See the comments in the code for more information.

```
public class RecursiveFileSearch
{
    static System.Collections.Specialized.StringCollection log = new
System.Collections.Specialized.StringCollection();

    static void Main()
    {
        // Start with drives if you have to search the entire computer.
        string[] drives = System.Environment.GetLogicalDrives();

        foreach (string dr in drives)
        {
            System.IO.DriveInfo di = new System.IO.DriveInfo(dr);

            // Here we skip the drive if it is not ready to be read. This
            // is not necessarily the appropriate action in all scenarios.
            if (!di.IsReady)
            {
                Console.WriteLine("The drive {0} could not be read", di.Name);
                continue;
            }
            System.IO.DirectoryInfo rootDir = di.RootDirectory;
            WalkDirectoryTree(rootDir);
        }

        // Write out all the files that could not be processed.
        Console.WriteLine("Files with restricted access:");
        foreach (string s in log)
        {
            Console.WriteLine(s);
        }
        // Keep the console window open in debug mode.
        Console.WriteLine("Press any key");
        Console.ReadKey();
    }

    static void WalkDirectoryTree(System.IO.DirectoryInfo root)
    {
        System.IO.FileInfo[] files = null;
        System.IO.DirectoryInfo[] subDirs = null;

        // First, process all the files directly under this folder
        try
        {
            files = root.GetFiles("*.");
        }
        // This is thrown if even one of the files requires permissions greater
        // than the application provides.
        catch (UnauthorizedAccessException e)
        {
            // This code just writes out the message and continues to recurse.
            // You may decide to do something different here. For example, you
            // can try to elevate your privileges and access the file again.
            log.Add(e.Message);
        }

        catch (System.IO.DirectoryNotFoundException e)
        {
            Console.WriteLine(e.Message);
        }
    }
}
```

```

if (files != null)
{
    foreach (System.IO.FileInfo fi in files)
    {
        // In this example, we only access the existing FileInfo object. If we
        // want to open, delete or modify the file, then
        // a try-catch block is required here to handle the case
        // where the file has been deleted since the call to TraverseTree().
        Console.WriteLine(fi.FullName);
    }

    // Now find all the subdirectories under this directory.
    subDirs = root.GetDirectories();

    foreach (System.IO.DirectoryInfo dirInfo in subDirs)
    {
        // Recursive call for each subdirectory.
        WalkDirectoryTree(dirInfo);
    }
}
}
}

```

The following example shows how to iterate through files and folders in a directory tree without using recursion. This technique uses the generic [Stack<T>](#) collection type, which is a last in first out (LIFO) stack.

The particular exceptions that are handled, and the particular actions that are performed on each file or folder, are provided as examples only. You should modify this code to meet your specific requirements. See the comments in the code for more information.

```

public class StackBasedIteration
{
    static void Main(string[] args)
    {
        // Specify the starting folder on the command line, or in
        // Visual Studio in the Project > Properties > Debug pane.
        TraverseTree(args[0]);

        Console.WriteLine("Press any key");
        Console.ReadKey();
    }

    public static void TraverseTree(string root)
    {
        // Data structure to hold names of subfolders to be
        // examined for files.
        Stack<string> dirs = new Stack<string>(20);

        if (!System.IO.Directory.Exists(root))
        {
            throw new ArgumentException();
        }
        dirs.Push(root);

        while (dirs.Count > 0)
        {
            string currentDir = dirs.Pop();
            string[] subDirs;
            try
            {
                subDirs = System.IO.Directory.GetDirectories(currentDir);
            }
            // An UnauthorizedAccessException exception will be thrown if we do not have
            // discovery permission on a folder or file. It may or may not be acceptable
            // to ignore the exception and continue enumerating the remaining files and

```

```

// folders. It is also possible (but unlikely) that a DirectoryNotFoundException
// will be raised. This will happen if currentDir has been deleted by
// another application or thread after our call to Directory.Exists. The
// choice of which exceptions to catch depends entirely on the specific task
// you are intending to perform and also on how much you know with certainty
// about the systems on which this code will run.
catch (UnauthorizedAccessException e)
{
    Console.WriteLine(e.Message);
    continue;
}
catch (System.IO.DirectoryNotFoundException e)
{
    Console.WriteLine(e.Message);
    continue;
}

string[] files = null;
try
{
    files = System.IO.Directory.GetFiles(currentDir);
}

catch (UnauthorizedAccessException e)
{
    Console.WriteLine(e.Message);
    continue;
}

catch (System.IO.DirectoryNotFoundException e)
{
    Console.WriteLine(e.Message);
    continue;
}

// Perform the required action on each file here.
// Modify this block to perform your required task.
foreach (string file in files)
{
    try
    {
        // Perform whatever action is required in your scenario.
        System.IO.FileInfo fi = new System.IO.FileInfo(file);
        Console.WriteLine("{0}: {1}, {2}", fi.Name, fi.Length, fi.CreationTime);
    }
    catch (System.IO.FileNotFoundException e)
    {
        // If file was deleted by a separate application
        // or thread since the call to TraverseTree()
        // then just continue.
        Console.WriteLine(e.Message);
        continue;
    }
}

// Push the subdirectories onto the stack for traversal.
// This could also be done before handing the files.
foreach (string str in subDirs)
    dirs.Push(str);
}
}
}

```

It is generally too time-consuming to test every folder to determine whether your application has permission to open it. Therefore, the code example just encloses that part of the operation in a `try/catch` block. You can modify the `catch` block so that when you are denied access to a folder, you try to elevate your permissions and

then access it again. As a rule, only catch those exceptions that you can handle without leaving your application in an unknown state.

If you must store the contents of a directory tree, either in memory or on disk, the best option is to store only the [FullName](#) property (of type `string`) for each file. You can then use this string to create a new [FileInfo](#) or [DirectoryInfo](#) object as necessary, or open any file that requires additional processing.

Robust Programming

Robust file iteration code must take into account many complexities of the file system. For more information on the Windows file system, see [NTFS overview](#).

How to get information about files, folders, and drives (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

In .NET, you can access file system information by using the following classes:

- [System.IO.FileInfo](#)
- [System.IO.DirectoryInfo](#)
- [System.IO.DriveInfo](#)
- [System.IO.Directory](#)
- [System.IO.File](#)

The [FileInfo](#) and [DirectoryInfo](#) classes represent a file or directory and contain properties that expose many of the file attributes that are supported by the NTFS file system. They also contain methods for opening, closing, moving, and deleting files and folders. You can create instances of these classes by passing a string that represents the name of the file, folder, or drive in to the constructor:

```
System.IO.DriveInfo di = new System.IO.DriveInfo(@"C:\");
```

You can also obtain the names of files, folders, or drives by using calls to [DirectoryInfo.GetDirectories](#), [DirectoryInfo.GetFiles](#), and [DriveInfo.RootDirectory](#).

The [System.IO.Directory](#) and [System.IO.File](#) classes provide static methods for retrieving information about directories and files.

Example

The following example shows various ways to access information about files and folders.

```
class FileSysInfo
{
    static void Main()
    {
        // You can also use System.Environment.GetLogicalDrives to
        // obtain names of all logical drives on the computer.
        System.IO.DriveInfo di = new System.IO.DriveInfo(@"C:\");
        Console.WriteLine(di.TotalFreeSpace);
        Console.WriteLine(di.VolumeLabel);

        // Get the root directory and print out some information about it.
        System.IO.DirectoryInfo dirInfo = di.RootDirectory;
        Console.WriteLine(dirInfo.Attributes.ToString());

        // Get the files in the directory and print out some information about them.
        System.IO.FileInfo[] fileNames = dirInfo.GetFiles("*.");

        foreach (System.IO.FileInfo fi in fileNames)
        {
            Console.WriteLine("{0}: {1}: {2}", fi.Name, fi.LastAccessTime, fi.Length);
        }

        // Get the subdirectories directly that is under the root.
```

```

// See "How to: Iterate Through a Directory Tree" for an example of how to
// iterate through an entire tree.
System.IO.DirectoryInfo[] dirInfos = dirInfo.GetDirectories("*.");

foreach (System.IO.DirectoryInfo d in dirInfos)
{
    Console.WriteLine(d.Name);
}

// The Directory and File classes provide several static methods
// for accessing files and directories.

// Get the current application directory.
string currentDirName = System.IO.Directory.GetCurrentDirectory();
Console.WriteLine(currentDirName);

// Get an array of file names as strings rather than FileInfo objects.
// Use this method when storage space is an issue, and when you might
// hold on to the file name reference for a while before you try to access
// the file.
string[] files = System.IO.Directory.GetFiles(currentDirName, "*.txt");

foreach (string s in files)
{
    // Create the FileInfo object only when needed to ensure
    // the information is as current as possible.
    System.IO.FileInfo fi = null;
    try
    {
        fi = new System.IO.FileInfo(s);
    }
    catch (System.IO.FileNotFoundException e)
    {
        // To inform the user and continue is
        // sufficient for this demonstration.
        // Your application may require different behavior.
        Console.WriteLine(e.Message);
        continue;
    }
    Console.WriteLine("{0} : {1}", fi.Name, fi.Directory);
}

// Change the directory. In this case, first check to see
// whether it already exists, and create it if it does not.
// If this is not appropriate for your application, you can
// handle the System.IO.IOException that will be raised if the
// directory cannot be found.
if (!System.IO.Directory.Exists(@"C:\Users\Public\TestFolder\"))
{
    System.IO.Directory.CreateDirectory(@"C:\Users\Public\TestFolder\");
}

System.IO.Directory.SetCurrentDirectory(@"C:\Users\Public\TestFolder\");

currentDirName = System.IO.Directory.GetCurrentDirectory();
Console.WriteLine(currentDirName);

// Keep the console window open in debug mode.
Console.WriteLine("Press any key to exit.");
Console.ReadKey();
}
}

```

Robust Programming

When you process user-specified path strings, you should also handle exceptions for the following conditions:

- The file name is malformed. For example, it contains invalid characters or only white space.
- The file name is null.
- The file name is longer than the system-defined maximum length.
- The file name contains a colon (:).

If the application does not have sufficient permissions to read the specified file, the `Exists` method returns `false` regardless of whether a path exists; the method does not throw an exception.

How to create a file or folder (C# Programming Guide)

12/28/2021 • 3 minutes to read • [Edit Online](#)

You can programmatically create a folder on your computer, create a subfolder, create a file in the subfolder, and write data to the file.

Example

```
public class CreateFileOrFolder
{
    static void Main()
    {
        // Specify a name for your top-level folder.
        string folderName = @"c:\Top-Level Folder";

        // To create a string that specifies the path to a subfolder under your
        // top-level folder, add a name for the subfolder to folderName.
        string pathString = System.IO.Path.Combine(folderName, "SubFolder");

        // You can write out the path name directly instead of using the Combine
        // method. Combine just makes the process easier.
        string pathString2 = @"c:\Top-Level Folder\SubFolder2";

        // You can extend the depth of your path if you want to.
        //pathString = System.IO.Path.Combine(pathString, "SubSubFolder");

        // Create the subfolder. You can verify in File Explorer that you have this
        // structure in the C: drive.
        //      Local Disk (C:)
        //          Top-Level Folder
        //              SubFolder
        System.IO.Directory.CreateDirectory(pathString);

        // Create a file name for the file you want to create.
        string fileName = System.IO.Path.GetRandomFileName();

        // This example uses a random string for the name, but you also can specify
        // a particular name.
        //string fileName = "MyNewFile.txt";

        // Use Combine again to add the file name to the path.
        pathString = System.IO.Path.Combine(pathString, fileName);

        // Verify the path that you have constructed.
        Console.WriteLine("Path to my file: {0}\n", pathString);

        // Check that the file doesn't already exist. If it doesn't exist, create
        // the file and write integers 0 - 99 to it.
        // DANGER: System.IO.File.Create will overwrite the file if it already exists.
        // This could happen even with random file names, although it is unlikely.
        if (!System.IO.File.Exists(pathString))
        {
            using (System.IO.FileStream fs = System.IO.File.Create(pathString))
            {
                for (byte i = 0; i < 100; i++)
                {
                    fs.WriteByte(i);
                }
            }
        }
    }
}
```

```

    }
    else
    {
        Console.WriteLine("File \"{0}\" already exists.", fileName);
        return;
    }

    // Read and display the data from your file.
    try
    {
        byte[] readBuffer = System.IO.File.ReadAllBytes(pathString);
        foreach (byte b in readBuffer)
        {
            Console.Write(b + " ");
        }
        Console.WriteLine();
    }
    catch (System.IO.IOException e)
    {
        Console.WriteLine(e.Message);
    }

    // Keep the console window open in debug mode.
    System.Console.WriteLine("Press any key to exit.");
    System.Console.ReadKey();
}
// Sample output:

// Path to my file: c:\Top-Level Folder\SubFolder\ttxvauxe.vv0

//0 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24 25 26 27 28 29
//30 31 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 48 49 50 51 52 53 54 55 56
// 57 58 59 60 61 62 63 64 65 66 67 68 69 70 71 72 73 74 75 76 77 78 79 80 81 82 8
//3 84 85 86 87 88 89 90 91 92 93 94 95 96 97 98 99
}

```

If the folder already exists, [CreateDirectory](#) does nothing, and no exception is thrown. However, [File.Create](#) replaces an existing file with a new file. The example uses an `if - else` statement to prevent an existing file from being replaced.

By making the following changes in the example, you can specify different outcomes based on whether a file with a certain name already exists. If such a file doesn't exist, the code creates one. If such a file exists, the code appends data to that file.

- Specify a non-random file name.

```

// Comment out the following line.
//string fileName = System.IO.Path.GetRandomFileName();

// Replace that line with the following assignment.
string fileName = "MyNewFile.txt";

```

- Replace the `if - else` statement with the `using` statement in the following code.

```

using (System.IO.FileStream fs = new System.IO.FileStream(pathString, FileMode.Append))
{
    for (byte i = 0; i < 100; i++)
    {
        fs.WriteByte(i);
    }
}

```

Run the example several times to verify that data is added to the file each time.

For more `FileMode` values that you can try, see [FileMode](#).

The following conditions may cause an exception:

- The folder name is malformed. For example, it contains illegal characters or is only white space ([ArgumentException](#) class). Use the [Path](#) class to create valid path names.
- The parent folder of the folder to be created is read-only ([IOException](#) class).
- The folder name is `null` ([ArgumentNullException](#) class).
- The folder name is too long ([PathTooLongException](#) class).
- The folder name is only a colon, ":" ([PathTooLongException](#) class).

.NET Security

An instance of the [SecurityException](#) class may be thrown in partial-trust situations.

If you don't have permission to create the folder, the example throws an instance of the [UnauthorizedAccessException](#) class.

How to copy, delete, and move files and folders (C# Programming Guide)

12/28/2021 • 3 minutes to read • [Edit Online](#)

The following examples show how to copy, move, and delete files and folders in a synchronous manner by using the [System.IO.File](#), [System.IO.Directory](#), [System.IO.FileInfo](#), and [System.IO.DirectoryInfo](#) classes from the [System.IO](#) namespace. These examples do not provide a progress bar or any other user interface. If you want to provide a standard progress dialog box, see [How to provide a progress dialog box for file operations](#).

Use [System.IO.FileSystemWatcher](#) to provide events that will enable you to calculate the progress when operating on multiple files. Another approach is to use platform invoke to call the relevant file-related methods in the Windows Shell. For information about how to perform these file operations asynchronously, see [Asynchronous File I/O](#).

Examples

The following example shows how to copy files and directories.

```

// Simple synchronous file copy operations with no user interface.
// To run this sample, first create the following directories and files:
// C:\Users\Public\TestFolder
// C:\Users\Public\TestFolder\test.txt
// C:\Users\Public\TestFolder\SubDir\test.txt
public class SimpleFileCopy
{
    static void Main()
    {
        string fileName = "test.txt";
        string sourcePath = @"C:\Users\Public\TestFolder";
        string targetPath = @"C:\Users\Public\TestFolder\SubDir";

        // Use Path class to manipulate file and directory paths.
        string sourceFile = System.IO.Path.Combine(sourcePath, fileName);
        string destFile = System.IO.Path.Combine(targetPath, fileName);

        // To copy a folder's contents to a new location:
        // Create a new target folder.
        // If the directory already exists, this method does not create a new directory.
        System.IO.Directory.CreateDirectory(targetPath);

        // To copy a file to another location and
        // overwrite the destination file if it already exists.
        System.IO.File.Copy(sourceFile, destFile, true);

        // To copy all the files in one directory to another directory.
        // Get the files in the source folder. (To recursively iterate through
        // all subfolders under the current directory, see
        // "How to: Iterate Through a Directory Tree.")
        // Note: Check for target path was performed previously
        //      in this code example.
        if (System.IO.Directory.Exists(sourcePath))
        {
            string[] files = System.IO.Directory.GetFiles(sourcePath);

            // Copy the files and overwrite destination files if they already exist.
            foreach (string s in files)
            {
                // Use static Path methods to extract only the file name from the path.
                fileName = System.IO.Path.GetFileName(s);
                destFile = System.IO.Path.Combine(targetPath, fileName);
                System.IO.File.Copy(s, destFile, true);
            }
        }
        else
        {
            Console.WriteLine("Source path does not exist!");
        }

        // Keep console window open in debug mode.
        Console.WriteLine("Press any key to exit.");
        Console.ReadKey();
    }
}

```

The following example shows how to move files and directories.

```
// Simple synchronous file move operations with no user interface.
public class SimpleFileMove
{
    static void Main()
    {
        string sourceFile = @"C:\Users\Public\public\test.txt";
        string destinationFile = @"C:\Users\Public\private\test.txt";

        // To move a file or folder to a new location:
        System.IO.File.Move(sourceFile, destinationFile);

        // To move an entire directory. To programmatically modify or combine
        // path strings, use the System.IO.Path class.
        System.IO.Directory.Move(@"C:\Users\Public\public\test\", @"C:\Users\Public\private");
    }
}
```

The following example shows how to delete files and directories.

```
// Simple synchronous file deletion operations with no user interface.
// To run this sample, create the following files on your drive:
// C:\Users\Public\DeleteTest\test1.txt
// C:\Users\Public\DeleteTest\test2.txt
// C:\Users\Public\DeleteTest\SubDir\test2.txt

public class SimpleFileDelete
{
    static void Main()
    {
        // Delete a file by using File class static method...
        if(System.IO.File.Exists(@"C:\Users\Public\DeleteTest\test.txt"))
        {
            // Use a try block to catch IOExceptions, to
            // handle the case of the file already being
            // opened by another process.
            try
            {
                System.IO.File.Delete(@"C:\Users\Public\DeleteTest\test.txt");
            }
            catch (System.IO.IOException e)
            {
                Console.WriteLine(e.Message);
                return;
            }
        }

        // ...or by using FileInfo instance method.
        System.IO.FileInfo fi = new System.IO.FileInfo(@"C:\Users\Public\DeleteTest\test2.txt");
        try
        {
            fi.Delete();
        }
        catch (System.IO.IOException e)
        {
            Console.WriteLine(e.Message);
        }

        // Delete a directory. Must be writable or empty.
        try
        {
            System.IO.Directory.Delete(@"C:\Users\Public\DeleteTest");
        }
        catch (System.IO.IOException e)
        {
            Console.WriteLine(e.Message);
        }
    }
}
```

```

// Delete a directory and all subdirectories with Directory static method...
if(System.IO.Directory.Exists(@"C:\Users\Public\DeleteTest"))
{
    try
    {
        System.IO.Directory.Delete(@"C:\Users\Public\DeleteTest", true);
    }

    catch (System.IO.IOException e)
    {
        Console.WriteLine(e.Message);
    }
}

// ...or with DirectoryInfo instance method.
System.IO.DirectoryInfo di = new System.IO.DirectoryInfo(@"C:\Users\Public\public");
// Delete this dir and all subdirs.
try
{
    {
        di.Delete(true);
    }
}
catch (System.IO.IOException e)
{
    Console.WriteLine(e.Message);
}
}
}

```

How to provide a progress dialog box for file operations (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

You can provide a standard dialog box that shows progress on file operations in Windows if you use the [CopyFile\(String, String, UIOption\)](#) method in the [Microsoft.VisualBasic](#) namespace.

NOTE

Your computer might show different names or locations for some of the Visual Studio user interface elements in the following instructions. The Visual Studio edition that you have and the settings that you use determine these elements. For more information, see [Personalizing the IDE](#).

To add a reference in Visual Studio

1. On the menu bar, choose **Project, Add Reference**.

The **Reference Manager** dialog box appears.

2. In the **Assemblies** area, choose **Framework** if it isn't already chosen.
3. In the list of names, select the **Microsoft.VisualBasic** check box, and then choose the **OK** button to close the dialog box.

Example

The following code copies the directory that `sourcePath` specifies into the directory that `destinationPath` specifies. This code also provides a standard dialog box that shows the estimated amount of time remaining before the operation finishes.

```
// The following using directive requires a project reference to Microsoft.VisualBasic.
using Microsoft.VisualBasic.FileIO;

class FileProgress
{
    static void Main()
    {
        // Specify the path to a folder that you want to copy. If the folder is small,
        // you won't have time to see the progress dialog box.
        string sourcePath = @"C:\Windows\symbols\";
        // Choose a destination for the copied files.
        string destinationPath = @"C:\TestFolder";

        FileSystem.CopyDirectory(sourcePath, destinationPath,
                                UIOption.AllDialogs);
    }
}
```

How to write to a text file (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

In this article, there are several examples showing various ways to write text to a file. The first two examples use static convenience methods on the [System.IO.File](#) class to write each element of any `IEnumerable<string>` and a `string` to a text file. The third example shows how to add text to a file when you have to process each line individually as you write to the file. In the first three examples, you overwrite all existing content in the file. The final example shows how to append text to an existing file.

These examples all write string literals to files. If you want to format text written to a file, use the [Format](#) method or C# [string interpolation](#) feature.

Write a collection of strings to a file

```
using System.IO;
using System.Threading.Tasks;

class WriteAllLines
{
    public static async Task ExampleAsync()
    {
        string[] lines =
        {
            "First line", "Second line", "Third line"
        };

        await File.WriteAllLinesAsync("WriteLines.txt", lines);
    }
}
```

The preceding source code example:

- Instantiates a string array with three values.
- Awaits a call to [File.WriteAllLinesAsync](#) which:
 - Asynchronously creates a file name *WriteLines.txt*. If the file already exists, it is overwritten.
 - Writes the given lines to the file.
 - Closes the file, automatically flushing and disposing as needed.

Write one string to a file

```

using System.IO;
using System.Threading.Tasks;

class WriteAllText
{
    public static async Task ExampleAsync()
    {
        string text =
            "A class is the most powerful data type in C#. Like a structure, " +
            "a class defines the data and behavior of the data type. ";

        await File.WriteAllTextAsync("WriteText.txt", text);
    }
}

```

The preceding source code example:

- Instantiates a string given the assigned string literal.
- Awaits a call to [File.WriteAllTextAsync](#) which:
 - Asynchronously creates a file name *WriteText.txt*. If the file already exists, it is overwritten.
 - Writes the given text to the file.
 - Closes the file, automatically flushing and disposing as needed.

Write selected strings from an array to a file

```

using System.IO;
using System.Threading.Tasks;

class StreamWriterOne
{
    public static async Task ExampleAsync()
    {
        string[] lines = { "First line", "Second line", "Third line" };
        using StreamWriter file = new("WriteLines2.txt");

        foreach (string line in lines)
        {
            if (!line.Contains("Second"))
            {
                await file.WriteLineAsync(line);
            }
        }
    }
}

```

The preceding source code example:

- Instantiates a string array with three values.
- Instantiates a [StreamWriter](#) with a file path of *WriteLines2.txt* as a [using declaration](#).
- Iterates through all the lines.
- Conditionally awaits a call to [StreamWriter.WriteLineAsync\(String\)](#), which writes the line to the file when the line doesn't contain `"Second"`.

Append text to an existing file

```
using System.IO;
using System.Threading.Tasks;

class StreamWriterTwo
{
    public static async Task ExampleAsync()
    {
        using StreamWriter file = new("WriteLines2.txt", append: true);
        await file.WriteLineAsync("Fourth line");
    }
}
```

The preceding source code example:

- Instantiates a string array with three values.
- Instantiates a [StreamWriter](#) with a file path of *WriteLines2.txt* as a [using declaration](#), passing in `true` to append.
- Awaits a call to [StreamWriter.WriteLineAsync\(String\)](#), which writes the string to the file as an appended line.

Exceptions

The following conditions may cause an exception:

- [InvalidOperationException](#): The file exists and is read-only.
- [PathTooLongException](#): The path name may be too long.
- [IOException](#): The disk may be full.

There are additional conditions that may cause exceptions when working with the file system, it is best to program defensively.

How to read from a text file (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

This example reads the contents of a text file by using the static methods [ReadAllText](#) and [ReadAllLines](#) from the [System.IO.File](#) class.

For an example that uses [StreamReader](#), see [How to read a text file one line at a time](#).

NOTE

The files that are used in this example are created in the topic [How to write to a text file](#).

Example

```
class ReadFromFile
{
    static void Main()
    {
        // The files used in this example are created in the topic
        // How to: Write to a Text File. You can change the path and
        // file name to substitute text files of your own.

        // Example #1
        // Read the file as one string.
        string text = System.IO.File.ReadAllText(@"C:\Users\Public\TestFolder\WriteText.txt");

        // Display the file contents to the console. Variable text is a string.
        System.Console.WriteLine("Contents of WriteText.txt = {0}", text);

        // Example #2
        // Read each line of the file into a string array. Each element
        // of the array is one line of the file.
        string[] lines = System.IO.File.ReadAllLines(@"C:\Users\Public\TestFolder\WriteLines2.txt");

        // Display the file contents by using a foreach loop.
        System.Console.WriteLine("Contents of Writelines2.txt = ");
        foreach (string line in lines)
        {
            // Use a tab to indent each line of the file.
            Console.WriteLine("\t" + line);
        }

        // Keep the console window open in debug mode.
        Console.WriteLine("Press any key to exit.");
        System.Console.ReadKey();
    }
}
```

Compiling the Code

Copy the code and paste it into a C# console application.

If you are not using the text files from [How to write to a text file](#), replace the argument to `ReadAllText` and `ReadAllLines` with the appropriate path and file name on your computer.

Robust Programming

The following conditions may cause an exception:

- The file doesn't exist or doesn't exist at the specified location. Check the path and the spelling of the file name.

.NET Security

Do not rely on the name of a file to determine the contents of the file. For example, the file `myFile.cs` might not be a C# source file.

How to read a text file one line at a time (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

This example reads the contents of a text file, one line at a time, into a string using the `ReadLines` method of the `File` class. Each text line is stored into the string `line` and displayed on the screen.

Example

```
int counter = 0;

// Read the file and display it line by line.
foreach (string line in System.IO.File.ReadLines(@"c:\test.txt"))
{
    System.Console.WriteLine(line);
    counter++;
}

System.Console.WriteLine("There were {0} lines.", counter);
// Suspend the screen.
System.Console.ReadLine();
```

Compiling the Code

Copy the code and paste it into the `Main` method of a console application.

Replace `"c:\test.txt"` with the actual file name.

Robust Programming

The following conditions may cause an exception:

- The file may not exist.

.NET Security

Do not make decisions about the contents of the file based on the name of the file. For example, the file `myFile.cs` may not be a C# source file.

How to create a key in the registry (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

This example adds the value pair, "Name" and "Isabella", to the current user's registry, under the key "Names".

Example

```
Microsoft.Win32.RegistryKey key;  
key = Microsoft.Win32.Registry.CurrentUser.CreateSubKey("Names");  
key.SetValue("Name", "Isabella");  
key.Close();
```

Compiling the Code

- Copy the code and paste it into the `Main` method of a console application.
- Replace the `Names` parameter with the name of a key that exists directly under the `HKEY_CURRENT_USER` node of the registry.
- Replace the `Name` parameter with the name of a value that exists directly under the `Names` node.

Robust Programming

Examine the registry structure to find a suitable location for your key. For example, you might want to open the `Software` key of the current user, and create a key with your company's name. Then add the registry values to your company's key.

The following conditions might cause an exception:

- The name of the key is null.
- The user does not have permissions to create registry keys.
- The key name exceeds the 255-character limit.
- The key is closed.
- The registry key is read-only.

.NET Security

It is more secure to write data to the user folder — `Microsoft.Win32.Registry.CurrentUser` — rather than to the local computer — `Microsoft.Win32.Registry.LocalMachine`.

When you create a registry value, you need to decide what to do if that value already exists. Another process, perhaps a malicious one, may have already created the value and have access to it. When you put data in the registry value, the data is available to the other process. To prevent this, use the.

`Overload:Microsoft.Win32.RegistryKey.GetValue` method. It returns null if the key does not already exist.

It is not secure to store secrets, such as passwords, in the registry as plain text, even if the registry key is protected by access control lists (ACL).

Interoperability (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Interoperability enables you to preserve and take advantage of existing investments in unmanaged code. Code that runs under the control of the common language runtime (CLR) is called *managed code*, and code that runs outside the CLR is called *unmanaged code*. COM, COM+, C++ components, ActiveX components, and Microsoft Windows API are examples of unmanaged code.

.NET enables interoperability with unmanaged code through platform invoke services, the [System.Runtime.InteropServices](#) namespace, C++ interoperability, and COM interoperability (COM interop).

In This Section

[Interoperability Overview](#)

Describes methods to interoperate between C# managed code and unmanaged code.

[How to access Office interop objects by using C# features](#)

Describes features that are introduced in Visual C# to facilitate Office programming.

[How to use indexed properties in COM interop programming](#)

Describes how to use indexed properties to access COM properties that have parameters.

[How to use platform invoke to play a WAV file](#)

Describes how to use platform invoke services to play a .wav sound file on the Windows operating system.

[Walkthrough: Office Programming](#)

Shows how to create an Excel workbook and a Word document that contains a link to the workbook.

[Example COM Class](#)

Demonstrates how to expose a C# class as a COM object.

C# Language Specification

For more information, see [Basic concepts](#) in the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

- [C# Programming Guide](#)
- [Interoperating with Unmanaged Code](#)
- [Walkthrough: Office Programming](#)

Interoperability Overview (C# Programming Guide)

12/28/2021 • 3 minutes to read • [Edit Online](#)

The topic describes methods to enable interoperability between C# managed code and unmanaged code.

Platform Invoke

Platform invoke is a service that enables managed code to call unmanaged functions that are implemented in dynamic link libraries (DLLs), such as those in the Microsoft Windows API. It locates and invokes an exported function and marshals its arguments (integers, strings, arrays, structures, and so on) across the interoperation boundary as needed.

For more information, see [Consuming Unmanaged DLL Functions](#) and [How to use platform invoke to play a WAV file](#).

NOTE

The [Common Language Runtime](#) (CLR) manages access to system resources. Calling unmanaged code that is outside the CLR bypasses this security mechanism, and therefore presents a security risk. For example, unmanaged code might call resources in unmanaged code directly, bypassing CLR security mechanisms. For more information, see [Security in .NET](#).

C++ Interop

You can use C++ interop, also known as It Just Works (IJW), to wrap a native C++ class so that it can be consumed by code that is authored in C# or another .NET language. To do this, you write C++ code to wrap a native DLL or COM component. Unlike other .NET languages, Visual C++ has interoperability support that enables managed and unmanaged code to be located in the same application and even in the same file. You then build the C++ code by using the `/clr` compiler switch to produce a managed assembly. Finally, you add a reference to the assembly in your C# project and use the wrapped objects just as you would use other managed classes.

Exposing COM Components to C#

You can consume a COM component from a C# project. The general steps are as follows:

1. Locate a COM component to use and register it. Use `regsvr32.exe` to register or un-register a COM DLL.
2. Add to the project a reference to the COM component or type library.

When you add the reference, Visual Studio uses the [Tlbimp.exe \(Type Library Importer\)](#), which takes a type library as input, to output a .NET interop assembly. The assembly, also named a runtime callable wrapper (RCW), contains managed classes and interfaces that wrap the COM classes and interfaces that are in the type library. Visual Studio adds to the project a reference to the generated assembly.

3. Create an instance of a class that is defined in the RCW. This, in turn, creates an instance of the COM object.
4. Use the object just as you use other managed objects. When the object is reclaimed by garbage collection, the instance of the COM object is also released from memory.

For more information, see [Exposing COM Components to the .NET Framework](#).

Exposing C# to COM

COM clients can consume C# types that have been correctly exposed. The basic steps to expose C# types are as follows:

1. Add interop attributes in the C# project.

You can make an assembly COM visible by modifying Visual C# project properties. For more information, see [Assembly Information Dialog Box](#).

2. Generate a COM type library and register it for COM usage.

You can modify Visual C# project properties to automatically register the C# assembly for COM interop. Visual Studio uses the [Regasm.exe \(Assembly Registration Tool\)](#), using the `/t1b` command-line switch, which takes a managed assembly as input, to generate a type library. This type library describes the `public` types in the assembly and adds registry entries so that COM clients can create managed classes.

For more information, see [Exposing .NET Framework Components to COM](#) and [Example COM Class](#).

How to access Office interop objects (C# Programming Guide)

12/28/2021 • 12 minutes to read • [Edit Online](#)

C# has features that simplify access to Office API objects. The new features include named and optional arguments, a new type called `dynamic`, and the ability to pass arguments to reference parameters in COM methods as if they were value parameters.

In this topic you will use the new features to write code that creates and displays a Microsoft Office Excel worksheet. You will then write code to add an Office Word document that contains an icon that is linked to the Excel worksheet.

To complete this walkthrough, you must have Microsoft Office Excel 2007 and Microsoft Office Word 2007, or later versions, installed on your computer.

NOTE

Your computer might show different names or locations for some of the Visual Studio user interface elements in the following instructions. The Visual Studio edition that you have and the settings that you use determine these elements. For more information, see [Personalizing the IDE](#).

To create a new console application

1. Start Visual Studio.
2. On the **File** menu, point to **New**, and then click **Project**. The **New Project** dialog box appears.
3. In the **Installed Templates** pane, expand **Visual C#**, and then click **Windows**.
4. Look at the top of the **New Project** dialog box to make sure that **.NET Framework 4** (or later version) is selected as a target framework.
5. In the **Templates** pane, click **Console Application**.
6. Type a name for your project in the **Name** field.
7. Click **OK**.

The new project appears in **Solution Explorer**.

To add references

1. In **Solution Explorer**, right-click your project's name and then click **Add Reference**. The **Add Reference** dialog box appears.
2. On the **Assemblies** page, select **Microsoft.Office.Interop.Word** in the **Component Name** list, and then hold down the CTRL key and select **Microsoft.Office.Interop.Excel**. If you do not see the assemblies, you may need to ensure they are installed and displayed. See [How to: Install Office Primary Interop Assemblies](#).
3. Click **OK**.

To add necessary using directives

1. In **Solution Explorer**, right-click the *Program.cs* file and then click **View Code**.
2. Add the following `using` directives to the top of the code file:

```
using Excel = Microsoft.Office.Interop.Excel;
using Word = Microsoft.Office.Interop.Word;
```

To create a list of bank accounts

1. Paste the following class definition into **Program.cs**, under the `Program` class.

```
public class Account
{
    public int ID { get; set; }
    public double Balance { get; set; }
}
```

2. Add the following code to the `Main` method to create a `bankAccounts` list that contains two accounts.

```
// Create a list of accounts.
var bankAccounts = new List<Account> {
    new Account {
        ID = 345678,
        Balance = 541.27
    },
    new Account {
        ID = 1230221,
        Balance = -127.44
    }
};
```

To declare a method that exports account information to Excel

1. Add the following method to the `Program` class to set up an Excel worksheet.

Method `Add` has an optional parameter for specifying a particular template. Optional parameters, new in C# 4, enable you to omit the argument for that parameter if you want to use the parameter's default value. Because no argument is sent in the following code, `Add` uses the default template and creates a new workbook. The equivalent statement in earlier versions of C# requires a placeholder argument:

```
ExcelApp.Workbooks.Add(Type.Missing) .
```

```
static void DisplayInExcel(IEnumerable<Account> accounts)
{
    var excelApp = new Excel.Application();
    // Make the object visible.
    excelApp.Visible = true;

    // Create a new, empty workbook and add it to the collection returned
    // by property Workbooks. The new workbook becomes the active workbook.
    // Add has an optional parameter for specifying a particular template.
    // Because no argument is sent in this example, Add creates a new workbook.
    excelApp.Workbooks.Add();

    // This example uses a single workSheet. The explicit type casting is
    // removed in a later procedure.
    Excel._Worksheet workSheet = (Excel.Worksheet)excelApp.ActiveSheet;
}
```

2. Add the following code at the end of `DisplayInExcel`. The code inserts values into the first two columns of the first row of the worksheet.

```
// Establish column headings in cells A1 and B1.
workSheet.Cells[1, "A"] = "ID Number";
workSheet.Cells[1, "B"] = "Current Balance";
```

3. Add the following code at the end of `DisplayInExcel`. The `foreach` loop puts the information from the list of accounts into the first two columns of successive rows of the worksheet.

```
var row = 1;
foreach (var acct in accounts)
{
    row++;
    workSheet.Cells[row, "A"] = acct.ID;
    workSheet.Cells[row, "B"] = acct.Balance;
}
```

4. Add the following code at the end of `DisplayInExcel` to adjust the column widths to fit the content.

```
workSheet.Columns[1].AutoFit();
workSheet.Columns[2].AutoFit();
```

Earlier versions of C# require explicit casting for these operations because `ExcelApp.Columns[1]` returns an `Object`, and `AutoFit` is an Excel [Range](#) method. The following lines show the casting.

```
((Excel.Range)workSheet.Columns[1]).AutoFit();
((Excel.Range)workSheet.Columns[2]).AutoFit();
```

C# 4, and later versions, converts the returned `Object` to `dynamic` automatically if the assembly is referenced by the [EmbedInteropTypes](#) compiler option or, equivalently, if the Excel **Embed Interop Types** property is set to true. True is the default value for this property.

To run the project

1. Add the following line at the end of `Main`.

```
// Display the list in an Excel spreadsheet.  
DisplayInExcel(bankAccounts);
```

2. Press CTRL+F5.

An Excel worksheet appears that contains the data from the two accounts.

To add a Word document

1. To illustrate additional ways in which C# 4, and later versions, enhances Office programming, the following code opens a Word application and creates an icon that links to the Excel worksheet.

Paste method `CreateIconInWordDoc`, provided later in this step, into the `Program` class.

`CreateIconInWordDoc` uses named and optional arguments to reduce the complexity of the method calls to `Add` and `PasteSpecial`. These calls incorporate two other new features introduced in C# 4 that simplify calls to COM methods that have reference parameters. First, you can send arguments to the reference parameters as if they were value parameters. That is, you can send values directly, without creating a variable for each reference parameter. The compiler generates temporary variables to hold the argument values, and discards the variables when you return from the call. Second, you can omit the `ref` keyword in the argument list.

The `Add` method has four reference parameters, all of which are optional. In C# 4.0 and later versions, you can omit arguments for any or all of the parameters if you want to use their default values. In C# 3.0 and earlier versions, an argument must be provided for each parameter, and the argument must be a variable because the parameters are reference parameters.

The `PasteSpecial` method inserts the contents of the Clipboard. The method has seven reference parameters, all of which are optional. The following code specifies arguments for two of them: `Link`, to create a link to the source of the Clipboard contents, and `DisplayAsIcon`, to display the link as an icon. In C# 4.0 and later versions, you can use named arguments for those two and omit the others. Although these are reference parameters, you do not have to use the `ref` keyword, or to create variables to send in as arguments. You can send the values directly. In C# 3.0 and earlier versions, you must supply a variable argument for each reference parameter.

```
static void CreateIconInWordDoc()  
{  
    var wordApp = new Word.Application();  
    wordApp.Visible = true;  
  
    // The Add method has four reference parameters, all of which are  
    // optional. Visual C# allows you to omit arguments for them if  
    // the default values are what you want.  
    wordApp.Documents.Add();  
  
    // PasteSpecial has seven reference parameters, all of which are  
    // optional. This example uses named arguments to specify values  
    // for two of the parameters. Although these are reference  
    // parameters, you do not need to use the ref keyword, or to create  
    // variables to send in as arguments. You can send the values directly.  
    wordApp.Selection.PasteSpecial( Link: true, DisplayAsIcon: true);  
}
```

In C# 3.0 and earlier versions of the language, the following more complex code is required.

```

static void CreateIconInWordDoc2008()
{
    var wordApp = new Word.Application();
    wordApp.Visible = true;

    // The Add method has four parameters, all of which are optional.
    // In Visual C# 2008 and earlier versions, an argument has to be sent
    // for every parameter. Because the parameters are reference
    // parameters of type object, you have to create an object variable
    // for the arguments that represents 'no value'.

    object useDefaultValue = Type.Missing;

    wordApp.Documents.Add(ref useDefaultValue, ref useDefaultValue,
        ref useDefaultValue, ref useDefaultValue);

    // PasteSpecial has seven reference parameters, all of which are
    // optional. In this example, only two of the parameters require
    // specified values, but in Visual C# 2008 an argument must be sent
    // for each parameter. Because the parameters are reference parameters,
    // you have to construct variables for the arguments.
    object link = true;
    object displayAsIcon = true;

    wordApp.Selection.PasteSpecial( ref useDefaultValue,
                                    ref link,
                                    ref useDefaultValue,
                                    ref displayAsIcon,
                                    ref useDefaultValue,
                                    ref useDefaultValue,
                                    ref useDefaultValue);
}

```

2. Add the following statement at the end of `Main`.

```

// Create a Word document that contains an icon that links to
// the spreadsheet.
CreateIconInWordDoc();

```

3. Add the following statement at the end of `DisplayInExcel`. The `Copy` method adds the worksheet to the Clipboard.

```

// Put the spreadsheet contents on the clipboard. The Copy method has one
// optional parameter for specifying a destination. Because no argument
// is sent, the destination is the Clipboard.
workSheet.Range["A1:B3"].Copy();

```

4. Press CTRL+F5.

A Word document appears that contains an icon. Double-click the icon to bring the worksheet to the foreground.

To set the Embed Interop Types property

1. Additional enhancements are possible when you call a COM type that does not require a primary interop assembly (PIA) at run time. Removing the dependency on PIAs results in version independence and easier deployment. For more information about the advantages of programming without PIAs, see [Walkthrough: Embedding Types from Managed Assemblies](#).

In addition, programming is easier because the types that are required and returned by COM methods

can be represented by using the type `dynamic` instead of `object`. Variables that have type `dynamic` are not evaluated until run time, which eliminates the need for explicit casting. For more information, see [Using Type dynamic](#).

In C# 4, embedding type information instead of using PIAs is default behavior. Because of that default, several of the previous examples are simplified because explicit casting is not required. For example, the declaration of `worksheet` in `DisplayInExcel` is written as

`Excel._Worksheet workSheet = excelApp.ActiveSheet` rather than `Excel._Worksheet workSheet = (Excel.Worksheet)excelApp.ActiveSheet`. The calls to `AutoFit` in the same method also would require explicit casting without the default, because `ExcelApp.Columns[1]` returns an `object`, and `AutoFit` is an Excel method. The following code shows the casting.

```
((Excel.Range)workSheet.Columns[1]).AutoFit();  
((Excel.Range)workSheet.Columns[2]).AutoFit();
```

2. To change the default and use PIAs instead of embedding type information, expand the **References** node in **Solution Explorer** and then select **Microsoft.Office.Interop.Excel** or **Microsoft.Office.Interop.Word**.
3. If you cannot see the **Properties** window, press **F4**.
4. Find **Embed Interop Types** in the list of properties, and change its value to **False**. Equivalently, you can compile by using the **References** compiler option instead of **EmbedInteropTypes** at a command prompt.

To add additional formatting to the table

1. Replace the two calls to `AutoFit` in `DisplayInExcel` with the following statement.

```
// Call to AutoFormat in Visual C# 2010.  
workSheet.Range["A1", "B3"].AutoFormat(  
    Excel.XlRangeAutoFormat.xlRangeAutoFormatClassic2);
```

The **AutoFormat** method has seven value parameters, all of which are optional. Named and optional arguments enable you to provide arguments for none, some, or all of them. In the previous statement, an argument is supplied for only one of the parameters, `Format`. Because `Format` is the first parameter in the parameter list, you do not have to provide the parameter name. However, the statement might be easier to understand if the parameter name is included, as is shown in the following code.

```
// Call to AutoFormat in Visual C# 2010.  
workSheet.Range["A1", "B3"].AutoFormat(Format:  
    Excel.XlRangeAutoFormat.xlRangeAutoFormatClassic2);
```

2. Press **CTRL+F5** to see the result. Other formats are listed in the **XlRangeAutoFormat** enumeration.
3. Compare the statement in step 1 with the following code, which shows the arguments that are required in C# 3.0 and earlier versions.

```
// The AutoFormat method has seven optional value parameters. The
// following call specifies a value for the first parameter, and uses
// the default values for the other six.

// Call to AutoFormat in Visual C# 2008. This code is not part of the
// current solution.
excelApp.get_Range("A1", "B4").AutoFormat(Excel.XlRangeAutoFormat.xlRangeAutoFormatTable3,
    Type.Missing, Type.Missing, Type.Missing, Type.Missing, Type.Missing,
    Type.Missing);
```

Example

The following code shows the complete example.

```
using System;
using System.Collections.Generic;
using System.Linq;
using Excel = Microsoft.Office.Interop.Excel;
using Word = Microsoft.Office.Interop.Word;

namespace OfficeProgramminWalkthruComplete
{
    class Walkthrough
    {
        static void Main(string[] args)
        {
            // Create a list of accounts.
            var bankAccounts = new List<Account>
            {
                new Account {
                    ID = 345678,
                    Balance = 541.27
                },
                new Account {
                    ID = 1230221,
                    Balance = -127.44
                }
            };

            // Display the list in an Excel spreadsheet.
            DisplayInExcel(bankAccounts);

            // Create a Word document that contains an icon that links to
            // the spreadsheet.
            CreateIconInWordDoc();
        }

        static void DisplayInExcel(IEnumerable<Account> accounts)
        {
            var excelApp = new Excel.Application();
            // Make the object visible.
            excelApp.Visible = true;

            // Create a new, empty workbook and add it to the collection returned
            // by property Workbooks. The new workbook becomes the active workbook.
            // Add has an optional parameter for specifying a particular template.
            // Because no argument is sent in this example, Add creates a new workbook.
            excelApp.Workbooks.Add();

            // This example uses a single worksheet.
            Excel._Worksheet workSheet = excelApp.ActiveSheet;

            // Earlier versions of C# require explicit casting.
            //Excel._Worksheet workSheet = (Excel.Worksheet)excelApp.ActiveSheet;
```

```

// Establish column headings in cells A1 and B1.
workSheet.Cells[1, "A"] = "ID Number";
workSheet.Cells[1, "B"] = "Current Balance";

var row = 1;
foreach (var acct in accounts)
{
    row++;
    workSheet.Cells[row, "A"] = acct.ID;
    workSheet.Cells[row, "B"] = acct.Balance;
}

workSheet.Columns[1].AutoFit();
workSheet.Columns[2].AutoFit();

// Call to AutoFormat in Visual C#. This statement replaces the
// two calls to AutoFit.
workSheet.Range["A1", "B3"].AutoFormat(
    Excel.XlRangeAutoFormat.xlRangeAutoFormatClassic2);

// Put the spreadsheet contents on the clipboard. The Copy method has one
// optional parameter for specifying a destination. Because no argument
// is sent, the destination is the Clipboard.
workSheet.Range["A1:B3"].Copy();
}

static void CreateIconInWordDoc()
{
    var wordApp = new Word.Application();
    wordApp.Visible = true;

    // The Add method has four reference parameters, all of which are
    // optional. Visual C# allows you to omit arguments for them if
    // the default values are what you want.
    wordApp.Documents.Add();

    // PasteSpecial has seven reference parameters, all of which are
    // optional. This example uses named arguments to specify values
    // for two of the parameters. Although these are reference
    // parameters, you do not need to use the ref keyword, or to create
    // variables to send in as arguments. You can send the values directly.
    wordApp.Selection.PasteSpecial(Link: true, DisplayAsIcon: true);
}

}

public class Account
{
    public int ID { get; set; }
    public double Balance { get; set; }
}
}

```

How to use indexed properties in COM interop programming (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Indexed properties improve the way in which COM properties that have parameters are consumed in C# programming. Indexed properties work together with other features in Visual C#, such as [named and optional arguments](#), a new type ([dynamic](#)), and [embedded type information](#), to enhance Microsoft Office programming.

In earlier versions of C#, methods are accessible as properties only if the `get` method has no parameters and the `set` method has one and only one value parameter. However, not all COM properties meet those restrictions. For example, the Excel `Range[]` property has a `get` accessor that requires a parameter for the name of the range. In the past, because you could not access the `Range` property directly, you had to use the `get_Range` method instead, as shown in the following example.

```
// Visual C# 2008 and earlier.
var excelApp = new Excel.Application();
// . . .
Excel.Range targetRange = excelApp.get_Range("A1", Type.Missing);
```

Indexed properties enable you to write the following instead:

```
// Visual C# 2010.
var excelApp = new Excel.Application();
// . . .
Excel.Range targetRange = excelApp.Range["A1"];
```

NOTE

The previous example also uses the [optional arguments](#) feature, which enables you to omit `Type.Missing`.

Similarly to set the value of the `Value` property of a `Range` object in C# 3.0 and earlier, two arguments are required. One supplies an argument for an optional parameter that specifies the type of the range value. The other supplies the value for the `Value` property. The following examples illustrate these techniques. Both set the value of the A1 cell to `Name`.

```
// Visual C# 2008.
targetRange.SetValue(Type.Missing, "Name");
// Or
targetRange.Value2 = "Name";
```

Indexed properties enable you to write the following code instead.

```
// Visual C# 2010.
targetRange.Value = "Name";
```

You cannot create indexed properties of your own. The feature only supports consumption of existing indexed properties.

Example

The following code shows a complete example. For more information about how to set up a project that accesses the Office API, see [How to access Office interop objects by using C# features](#).

```
// You must add a reference to Microsoft.Office.Interop.Excel to run
// this example.
using System;
using Excel = Microsoft.Office.Interop.Excel;

namespace IndexedProperties
{
    class Program
    {
        static void Main(string[] args)
        {
            CSharp2010();
            //CSharp2008();
        }

        static void CSharp2010()
        {
            var excelApp = new Excel.Application();
            excelApp.Workbooks.Add();
            excelApp.Visible = true;

            Excel.Range targetRange = excelApp.Range["A1"];
            targetRange.Value = "Name";
        }

        static void CSharp2008()
        {
            var excelApp = new Excel.Application();
            excelApp.Workbooks.Add(Type.Missing);
            excelApp.Visible = true;

            Excel.Range targetRange = excelApp.get_Range("A1", Type.Missing);
            targetRange.set_Value(Type.Missing, "Name");
            // Or
            //targetRange.Value2 = "Name";
        }
    }
}
```

How to use platform invoke to play a WAV file (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The following C# code example illustrates how to use platform invoke services to play a WAV sound file on the Windows operating system.

Example

This example code uses [DllImportAttribute](#) to import `winmm.dll`'s `PlaySound` method entry point as `Form1.PlaySound()`. The example has a simple Windows Form with a button. Clicking the button opens a standard windows [OpenFileDialog](#) dialog box so that you can open a file to play. When a wave file is selected, it is played by using the `PlaySound()` method of the `winmm.dll` library. For more information about this method, see [Using the PlaySound function with Waveform-Audio Files](#). Browse and select a file that has a .wav extension, and then click **Open** to play the wave file by using platform invoke. A text box shows the full path of the file selected.

The **Open Files** dialog box is filtered to show only files that have a .wav extension through the filter settings:

```
dialog1.Filter = "Wav Files (*.wav)|*.wav";
```

```

using System.Windows.Forms;
using System.Runtime.InteropServices;

namespace WinSound
{
    public partial class Form1 : Form
    {
        private TextBox textBox1;
        private Button button1;

        public Form1() // Constructor.
        {
            InitializeComponent();
        }

        [DllImport("winmm.DLL", EntryPoint = "PlaySound", SetLastError = true, CharSet = CharSet.Unicode,
        ThrowOnUnmappableChar = true)]
        private static extern bool PlaySound(string szSound, System.IntPtr hMod, PlaySoundFlags flags);

        [System.Flags]
        public enum PlaySoundFlags : int
        {
            SND_SYNC = 0x0000,
            SND_ASYNC = 0x0001,
            SND_NODEFAULT = 0x0002,
            SND_LOOP = 0x0008,
            SND_NOSTOP = 0x0010,
            SND_NOWAIT = 0x00002000,
            SND_FILENAME = 0x00020000,
            SND_RESOURCE = 0x00040004
        }

        private void button1_Click(object sender, System.EventArgs e)
        {
            var dialog1 = new OpenFileDialog();

            dialog1.Title = "Browse to find sound file to play";
            dialog1.InitialDirectory = @"c:\";
            dialog1.Filter = "Wav Files (*.wav)|*.wav";
            dialog1.FilterIndex = 2;
            dialog1.RestoreDirectory = true;

            if (dialog1.ShowDialog() == DialogResult.OK)
            {
                textBox1.Text = dialog1.FileName;
                PlaySound(dialog1.FileName, new System.IntPtr(), PlaySoundFlags.SND_SYNC);
            }
        }

        private void Form1_Load(object sender, EventArgs e)
        {
            // Including this empty method in the sample because in the IDE,
            // when users click on the form, generates code that looks for a default method
            // with this name. We add it here to prevent confusion for those using the samples.
        }
    }
}

```

Compiling the code

1. Create a new C# Windows Forms Application project in Visual Studio and name it **WinSound**.
2. Copy the code above, and paste it over the contents of the *Form1.cs* file.
3. Copy the following code, and paste it in the *Form1.Designer.cs* file, in the `InitializeComponent()` method,

after any existing code.

```
this.button1 = new System.Windows.Forms.Button();
this.textBox1 = new System.Windows.Forms.TextBox();
this.SuspendLayout();
//
// button1
//
this.button1.Location = new System.Drawing.Point(192, 40);
this.button1.Name = "button1";
this.button1.Size = new System.Drawing.Size(88, 24);
this.button1.TabIndex = 0;
this.button1.Text = "Browse";
this.button1.Click += new System.EventHandler(this.button1_Click);
//
// textBox1
//
this.textBox1.Location = new System.Drawing.Point(8, 40);
this.textBox1.Name = "textBox1";
this.textBox1.Size = new System.Drawing.Size(168, 20);
this.textBox1.TabIndex = 1;
this.textBox1.Text = "File path";
//
// Form1
//
this.AutoScaleDimensions = new System.Drawing.SizeF(5, 13);
this.ClientSize = new System.Drawing.Size(292, 266);
this.Controls.Add(this.textBox1);
this.Controls.Add(this.button1);
this.Name = "Form1";
this.Text = "Platform Invoke WinSound C#";
this.ResumeLayout(false);
this.PerformLayout();
```

4. Compile and run the code.

Walkthrough: Office Programming (C# and Visual Basic)

12/28/2021 • 11 minutes to read • [Edit Online](#)

Visual Studio offers features in C# and Visual Basic that improve Microsoft Office programming. Helpful C# features include named and optional arguments and return values of type `dynamic`. In COM programming, you can omit the `ref` keyword and gain access to indexed properties. Features in Visual Basic include auto-implemented properties, statements in lambda expressions, and collection initializers.

Both languages enable embedding of type information, which allows deployment of assemblies that interact with COM components without deploying primary interop assemblies (PIAs) to the user's computer. For more information, see [Walkthrough: Embedding Types from Managed Assemblies](#).

This walkthrough demonstrates these features in the context of Office programming, but many of these features are also useful in general programming. In the walkthrough, you use an Excel Add-in application to create an Excel workbook. Next, you create a Word document that contains a link to the workbook. Finally, you see how to enable and disable the PIA dependency.

Prerequisites

You must have Microsoft Office Excel and Microsoft Office Word installed on your computer to complete this walkthrough.

NOTE

Your computer might show different names or locations for some of the Visual Studio user interface elements in the following instructions. The Visual Studio edition that you have and the settings that you use determine these elements. For more information, see [Personalizing the IDE](#).

To set up an Excel Add-in application

1. Start Visual Studio.
2. On the **File** menu, point to **New**, and then click **Project**.
3. In the **Installed Templates** pane, expand **Visual Basic** or **Visual C#**, expand **Office**, and then click the version year of the Office product.
4. In the **Templates** pane, click **Excel <version> Add-in**.
5. Look at the top of the **Templates** pane to make sure that **.NET Framework 4**, or a later version, appears in the **Target Framework** box.
6. Type a name for your project in the **Name** box, if you want to.
7. Click **OK**.
8. The new project appears in **Solution Explorer**.

To add references

1. In **Solution Explorer**, right-click your project's name and then click **Add Reference**. The **Add Reference** dialog box appears.

2. On the **Assemblies** tab, select **Microsoft.Office.Interop.Excel**, version `<version>.0.0.0` (for a key to the Office product version numbers, see [Microsoft Versions](#)), in the **Component Name** list, and then hold down the CTRL key and select **Microsoft.Office.Interop.Word**, `version <version>.0.0.0`. If you do not see the assemblies, you may need to ensure they are installed and displayed (see [How to: Install Office Primary Interop Assemblies](#)).
3. Click **OK**.

To add necessary Imports statements or using directives

1. In **Solution Explorer**, right-click the **ThisAddIn.vb** or **ThisAddIn.cs** file and then click **View Code**.
2. Add the following `Imports` statements (Visual Basic) or `using` directives (C#) to the top of the code file if they are not already present.

```
using System.Collections.Generic;
using Excel = Microsoft.Office.Interop.Excel;
using Word = Microsoft.Office.Interop.Word;
```

```
Imports Microsoft.Office.Interop
```

To create a list of bank accounts

1. In **Solution Explorer**, right-click your project's name, click **Add**, and then click **Class**. Name the class **Account.vb** if you are using Visual Basic or **Account.cs** if you are using C#. Click **Add**.
2. Replace the definition of the `Account` class with the following code. The class definitions use *auto-implemented properties*. For more information, see [Auto-Implemented Properties](#).

```
class Account
{
    public int ID { get; set; }
    public double Balance { get; set; }
}
```

```
Public Class Account
    Property ID As Integer = -1
    Property Balance As Double
End Class
```

3. To create a `bankAccounts` list that contains two accounts, add the following code to the `ThisAddIn_Startup` method in *ThisAddIn.vb* or *ThisAddIn.cs*. The list declarations use *collection initializers*. For more information, see [Collection Initializers](#).

```
var bankAccounts = new List<Account>
{
    new Account
    {
        ID = 345,
        Balance = 541.27
    },
    new Account
    {
        ID = 123,
        Balance = -127.44
    }
};
```

```
Dim bankAccounts As New List(Of Account) From {
    New Account With {
        .ID = 345,
        .Balance = 541.27
    },
    New Account With {
        .ID = 123,
        .Balance = -127.44
    }
}
```

To export data to Excel

1. In the same file, add the following method to the `ThisAddIn` class. The method sets up an Excel workbook and exports data to it.

```
void DisplayInExcel(IEnumerable<Account> accounts,
    Action<Account, Excel.Range> DisplayFunc)
{
    var excelApp = this.Application;
    // Add a new Excel workbook.
    excelApp.Workbooks.Add();
    excelApp.Visible = true;
    excelApp.Range["A1"].Value = "ID";
    excelApp.Range["B1"].Value = "Balance";
    excelApp.Range["A2"].Select();

    foreach (var ac in accounts)
    {
        DisplayFunc(ac, excelApp.ActiveCell);
        excelApp.ActiveCell.Offset[1, 0].Select();
    }
    // Copy the results to the Clipboard.
    excelApp.Range["A1:B3"].Copy();
}
```

```
Sub DisplayInExcel(ByVal accounts As IEnumerable(Of Account),
    ByVal DisplayAction As Action(Of Account, Excel.Range))

    With Me.Application
        ' Add a new Excel workbook.
        .Workbooks.Add()
        .Visible = True
        .Range("A1").Value = "ID"
        .Range("B1").Value = "Balance"
        .Range("A2").Select()

        For Each ac In accounts
            DisplayAction(ac, .ActiveCell)
            .ActiveCell.Offset(1, 0).Select()
        Next

        ' Copy the results to the Clipboard.
        .Range("A1:B3").Copy()
    End With
End Sub
```

Two new C# features are used in this method. Both of these features already exist in Visual Basic.

- Method `Add` has an *optional parameter* for specifying a particular template. Optional parameters, new in C# 4, enable you to omit the argument for that parameter if you want to use the parameter's default value. Because no argument is sent in the previous example, `Add` uses the

default template and creates a new workbook. The equivalent statement in earlier versions of C# requires a placeholder argument: `excelApp.Workbooks.Add(Type.Missing)`.

For more information, see [Named and Optional Arguments](#).

- The `Range` and `Offset` properties of the `Range` object use the *indexed properties* feature. This feature enables you to consume these properties from COM types by using the following typical C# syntax. Indexed properties also enable you to use the `Value` property of the `Range` object, eliminating the need to use the `Value2` property. The `Value` property is indexed, but the index is optional. Optional arguments and indexed properties work together in the following example.

```
// Visual C# 2010 provides indexed properties for COM programming.
excelApp.Range["A1"].Value = "ID";
excelApp.ActiveCell.Offset[1, 0].Select();
```

In earlier versions of the language, the following special syntax is required.

```
// In Visual C# 2008, you cannot access the Range, Offset, and Value
// properties directly.
excelApp.get_Range("A1").Value2 = "ID";
excelApp.ActiveCell.get_Offset(1, 0).Select();
```

You cannot create indexed properties of your own. The feature only supports consumption of existing indexed properties.

For more information, see [How to use indexed properties in COM interop programming](#).

2. Add the following code at the end of `DisplayInExcel` to adjust the column widths to fit the content.

```
excelApp.Columns[1].AutoFit();
excelApp.Columns[2].AutoFit();
```

```
' Add the following two lines at the end of the With statement.
.Columns(1).AutoFit()
.Columns(2).AutoFit()
```

These additions demonstrate another feature in C#: treating `Object` values returned from COM hosts such as Office as if they have type `dynamic`. This happens automatically when **Embed Interop Types** is set to its default value, `True`, or, equivalently, when the assembly is referenced by the **EmbedInteropTypes** compiler option. Type `dynamic` allows late binding, already available in Visual Basic, and avoids the explicit casting required in C# 3.0 and earlier versions of the language.

For example, `excelApp.Columns[1]` returns an `Object`, and `AutoFit` is an Excel `Range` method. Without `dynamic`, you must cast the object returned by `excelApp.Columns[1]` as an instance of `Range` before calling method `AutoFit`.

```
// Casting is required in Visual C# 2008.
((Excel.Range)excelApp.Columns[1]).AutoFit();

// Casting is not required in Visual C# 2010.
excelApp.Columns[1].AutoFit();
```

For more information about embedding interop types, see procedures "To find the PIA reference" and "To restore the PIA dependency" later in this topic. For more information about `dynamic`, see [dynamic](#) or

To invoke DisplayInExcel

1. Add the following code at the end of the `ThisAddIn_StartUp` method. The call to `DisplayInExcel` contains two arguments. The first argument is the name of the list of accounts to be processed. The second argument is a multiline lambda expression that defines how the data is to be processed. The `ID` and `balance` values for each account are displayed in adjacent cells, and the row is displayed in red if the balance is less than zero. For more information, see [Lambda Expressions](#).

```
DisplayInExcel(bankAccounts, (account, cell) =>
// This multiline lambda expression sets custom processing rules
// for the bankAccounts.
{
    cell.Value = account.ID;
    cell.Offset[0, 1].Value = account.Balance;
    if (account.Balance < 0)
    {
        cell.Interior.Color = 255;
        cell.Offset[0, 1].Interior.Color = 255;
    }
});
```

```
DisplayInExcel(bankAccounts,
    Sub(account, cell)
        ' This multiline lambda expression sets custom
        ' processing rules for the bankAccounts.
        cell.Value = account.ID
        cell.Offset(0, 1).Value = account.Balance

        If account.Balance < 0 Then
            cell.Interior.Color = RGB(255, 0, 0)
            cell.Offset(0, 1).Interior.Color = RGB(255, 0, 0)
        End If
    End Sub)
```

2. To run the program, press F5. An Excel worksheet appears that contains the data from the accounts.

To add a Word document

1. Add the following code at the end of the `ThisAddIn_StartUp` method to create a Word document that contains a link to the Excel workbook.

```
var wordApp = new Word.Application();
wordApp.Visible = true;
wordApp.Documents.Add();
wordApp.Selection.PasteSpecial(Link: true, DisplayAsIcon: true);
```

```
Dim wordApp As New Word.Application
wordApp.Visible = True
wordApp.Documents.Add()
wordApp.Selection.PasteSpecial(Link:=True, DisplayAsIcon:=True)
```

This code demonstrates several of the new features in C#: the ability to omit the `ref` keyword in COM programming, named arguments, and optional arguments. These features already exist in Visual Basic. The [PasteSpecial](#) method has seven parameters, all of which are defined as optional reference parameters. Named and optional arguments enable you to designate the parameters you want to access by name and to send arguments to only those parameters. In this example, arguments are sent to

indicate that a link to the workbook on the Clipboard should be created (parameter `Link`) and that the link is to be displayed in the Word document as an icon (parameter `DisplayAsIcon`). Visual C# also enables you to omit the `ref` keyword for these arguments.

To run the application

1. Press F5 to run the application. Excel starts and displays a table that contains the information from the two accounts in `bankAccounts`. Then a Word document appears that contains a link to the Excel table.

To clean up the completed project

1. In Visual Studio, click **Clean Solution** on the **Build** menu. Otherwise, the add-in will run every time that you open Excel on your computer.

To find the PIA reference

1. Run the application again, but do not click **Clean Solution**.
2. Select the **Start**. Locate **Microsoft Visual Studio <version>** and open a developer command prompt.
3. Type `ildasm` in the Developer Command Prompt for Visual Studio window, and then press ENTER. The IL DASM window appears.
4. On the **File** menu in the IL DASM window, select **File > Open**. Double-click **Visual Studio <version>**, and then double-click **Projects**. Open the folder for your project, and look in the bin/Debug folder for *your project name.dll*. Double-click *your project name.dll*. A new window displays your project's attributes, in addition to references to other modules and assemblies. Note that namespaces `Microsoft.Office.Interop.Excel` and `Microsoft.Office.Interop.Word` are included in the assembly. By default in Visual Studio, the compiler imports the types you need from a referenced PIA into your assembly.

For more information, see [How to: View Assembly Contents](#).

5. Double-click the **MANIFEST** icon. A window appears that contains a list of assemblies that contain items referenced by the project. `Microsoft.Office.Interop.Excel` and `Microsoft.Office.Interop.Word` are not included in the list. Because the types your project needs have been imported into your assembly, references to a PIA are not required. This makes deployment easier. The PIAs do not have to be present on the user's computer, and because an application does not require deployment of a specific version of a PIA, applications can be designed to work with multiple versions of Office, provided that the necessary APIs exist in all versions.

Because deployment of PIAs is no longer necessary, you can create an application in advanced scenarios that works with multiple versions of Office, including earlier versions. However, this works only if your code does not use any APIs that are not available in the version of Office you are working with. It is not always clear whether a particular API was available in an earlier version, and for that reason working with earlier versions of Office is not recommended.

NOTE

Office did not publish PIAs before Office 2003. Therefore, the only way to generate an interop assembly for Office 2002 or earlier versions is by importing the COM reference.

6. Close the manifest window and the assembly window.

To restore the PIA dependency

1. In **Solution Explorer**, click the **Show All Files** button. Expand the **References** folder and select `Microsoft.Office.Interop.Excel`. Press F4 to display the **Properties** window.
2. In the **Properties** window, change the **Embed Interop Types** property from **True** to **False**.

3. Repeat steps 1 and 2 in this procedure for `Microsoft.Office.Interop.Word`.
4. In C#, comment out the two calls to `Autofit` at the end of the `DisplayInExcel` method.
5. Press F5 to verify that the project still runs correctly.
6. Repeat steps 1-3 from the previous procedure to open the assembly window. Notice that `Microsoft.Office.Interop.Word` and `Microsoft.Office.Interop.Excel` are no longer in the list of embedded assemblies.
7. Double-click the **MANIFEST** icon and scroll through the list of referenced assemblies. Both `Microsoft.Office.Interop.Word` and `Microsoft.Office.Interop.Excel` are in the list. Because the application references the Excel and Word PIAs, and the **Embed Interop Types** property is set to **False**, both assemblies must exist on the end user's computer.
8. In Visual Studio, click **Clean Solution** on the **Build** menu to clean up the completed project.

Example COM Class (C# Programming Guide)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The following is an example of a class that you would expose as a COM object. After this code has been placed in a .cs file and added to your project, set the **Register for COM Interop** property to **True**. For more information, see [How to: Register a Component for COM Interop](#).

Exposing Visual C# objects to COM requires declaring a class interface, an events interface if it is required, and the class itself. Class members must follow these rules to be visible to COM:

- The class must be public.
- Properties, methods, and events must be public.
- Properties and methods must be declared on the class interface.
- Events must be declared in the event interface.

Other public members in the class that are not declared in these interfaces will not be visible to COM, but they will be visible to other .NET objects.

To expose properties and methods to COM, you must declare them on the class interface and mark them with a `DispId` attribute, and implement them in the class. The order in which the members are declared in the interface is the order used for the COM vtable.

To expose events from your class, you must declare them on the events interface and mark them with a `DispId` attribute. The class should not implement this interface.

The class implements the class interface; it can implement more than one interface, but the first implementation will be the default class interface. Implement the methods and properties exposed to COM here. They must be marked public and must match the declarations in the class interface. Also, declare the events raised by the class here. They must be marked public and must match the declarations in the events interface.

Example

```
using System.Runtime.InteropServices;

namespace project_name
{
    [Guid("EAA4976A-45C3-4BC5-BC0B-E474F4C3C83F")]
    public interface ComClass1Interface
    {
    }

    [Guid("7BD20046-DF8C-44A6-8F6B-687FAA26FA71"),
        InterfaceType(ComInterfaceType.InterfaceIsIDispatch)]
    public interface ComClass1Events
    {
    }

    [Guid("0D53A3E8-E51A-49C7-944E-E72A2064F938"),
        ClassInterface(ClassInterfaceType.None),
        ComSourceInterfaces(typeof(ComClass1Events))]
    public class ComClass1 : ComClass1Interface
    {
    }
}
```

C# reference

12/28/2021 • 3 minutes to read • [Edit Online](#)

This section provides reference material about C# keywords, operators, special characters, preprocessor directives, compiler options, and compiler errors and warnings.

In this section

[C# Keywords](#)

Provides links to information about C# keywords and syntax.

[C# Operators](#)

Provides links to information about C# operators and syntax.

[C# Special Characters](#)

Provides links to information about special contextual characters in C# and their usage.

[C# Preprocessor Directives](#)

Provides links to information about compiler commands for embedding in C# source code.

[C# Compiler Options](#)

Includes information about compiler options and how to use them.

[C# Compiler Errors](#)

Includes code snippets that demonstrate the cause and correction of C# compiler errors and warnings.

[C# Language Specification](#)

The C# 6.0 language specification. This is a draft proposal for the C# 6.0 language. This document will be refined through work with the ECMA C# standards committee. Version 5.0 has been released in December 2017 as the [Standard ECMA-334 5th Edition](#) document.

The features that have been implemented in C# versions after 6.0 are represented in language specification proposals. These documents describe the deltas to the language spec in order to add these new features. These are in draft proposal form. These specifications will be refined and submitted to the ECMA standards committee for formal review and incorporation into a future version of the C# Standard.

[C# 7.0 Specification Proposals](#)

There are a number of new features implemented in C# 7.0. They include pattern matching, local functions, out variable declarations, throw expressions, binary literals, and digit separators. This folder contains the specifications for each of those features.

[C# 7.1 Specification Proposals](#)

There are new features added in C# 7.1. First, you can write a `Main` method that returns `Task` or `Task<int>`. This enables you to add the `async` modifier to `Main`. The `default` expression can be used without a type in locations where the type can be inferred. Also, tuple member names can be inferred. Finally, pattern matching can be used with generics.

[C# 7.2 Specification Proposals](#)

C# 7.2 added a number of small features. You can pass arguments by readonly reference using the `in` keyword. There are a number of low-level changes to support compile-time safety for `Span` and related types. You can use named arguments where later arguments are positional, in some situations. The `private protected` access modifier enables you to specify that callers are limited to derived types implemented in the same assembly. The `?:` operator can resolve to a reference to a variable. You can also format hexadecimal and binary numbers

using a leading digit separator.

[C# 7.3 Specification Proposals](#)

C# 7.3 is another point release that includes several small updates. You can use new constraints on generic type parameters. Other changes make it easier to work with `fixed` fields, including using `stackalloc` allocations. Local variables declared with the `ref` keyword may be reassigned to refer to new storage. You can place attributes on auto-implemented properties that target the compiler-generated backing field. Expression variables can be used in initializers. Tuples can be compared for equality (or inequality). There have also been some improvements to overload resolution.

[C# 8.0 Specification Proposals](#)

C# 8.0 is available with .NET Core 3.0. The features include nullable reference types, recursive pattern matching, default interface methods, async streams, ranges and indexes, pattern based using and using declarations, null coalescing assignment, and readonly instance members.

[C# 9 Specification Proposals](#)

C# 9 is available with .NET 5. The features include records, top-level statements, pattern matching enhancements, init only setters, target-typed new expressions, module initializers, extending partial methods, static anonymous functions, target-typed conditional expressions, covariant return types, extension GetEnumerator in foreach loops, lambda discard parameters, attributes on local functions, native sized integers, function pointers, suppress emitting localsinit flag, and unconstrained type parameter annotations.

[C# 10 Specification Proposals](#)

C# 10 is available with .NET 6. The features include record structs, parameterless struct constructors, global using directives, file-scoped namespaces, extended property patterns, improved interpolated strings, constant interpolated strings, lambda improvements, caller-argument expression, enhanced `#line` directives, generic attributes, improved definite assignment analysis, and `AsyncMethodBuilder` override.

C# language versioning

12/28/2021 • 4 minutes to read • [Edit Online](#)

The latest C# compiler determines a default language version based on your project's target framework or frameworks. Visual Studio doesn't provide a UI to change the value, but you can change it by editing the *csproj* file. The choice of default ensures that you use the latest language version compatible with your target framework. You benefit from access to the latest language features compatible with your project's target. This default choice also ensures you don't use a language that requires types or runtime behavior not available in your target framework. Choosing a language version newer than the default can cause hard to diagnose compile-time and runtime errors.

The rules in this article apply to the compiler delivered with Visual Studio 2019 or the .NET SDK. The C# compilers that are part of the Visual Studio 2017 installation or earlier .NET Core SDK versions target C# 7.0 by default.

C# 8.0 is supported only on .NET Core 3.x and newer versions. Many of the newest features require library and runtime features introduced in .NET Core 3.x:

- [Default interface implementation](#) requires new features in the .NET Core 3.0 CLR.
- [Async streams](#) require the new types [System.IAsyncDisposable](#), [System.Collections.Generic.IAsyncEnumerable<T>](#), and [System.Collections.Generic.IAsyncEnumerator<T>](#).
- [Indices and ranges](#) require the new types [System.Index](#) and [System.Range](#).
- [Nullable reference types](#) make use of several [attributes](#) to provide better warnings. Those attributes were added in .NET Core 3.0. Other target frameworks haven't been annotated with any of these attributes. That means nullable warnings may not accurately reflect potential issues.

C# 9 is supported only on .NET 5 and newer versions.

C# 10 is supported only on .NET 6 and newer versions.

Defaults

The compiler determines a default based on these rules:

TARGET FRAMEWORK	VERSION	C# LANGUAGE VERSION DEFAULT
.NET	6.x	C# 10
.NET	5.x	C# 9.0
.NET Core	3.x	C# 8.0
.NET Core	2.x	C# 7.3
.NET Standard	2.1	C# 8.0
.NET Standard	2.0	C# 7.3
.NET Standard	1.x	C# 7.3

TARGET FRAMEWORK	VERSION	C# LANGUAGE VERSION DEFAULT
.NET Framework	all	C# 7.3

When your project targets a preview framework that has a corresponding preview language version, the language version used is the preview language version. You use the latest features with that preview in any environment, without affecting projects that target a released .NET Core version.

IMPORTANT

Visual Studio 2017 added a `<LangVersion>latest</LangVersion>` entry to any project files it created. That meant C# 7.0 when it was added. However, once you upgrade to Visual Studio 2019, that means the latest released version, regardless of the target framework. These projects now [override the default behavior](#). You should edit the project file and remove that node. Then, your project will use the compiler version recommended for your target framework.

Override a default

If you must specify your C# version explicitly, you can do so in several ways:

- Manually edit your [project file](#).
- Set the language version [for multiple projects in a subdirectory](#).
- Configure the [LangVersion compiler option](#).

TIP

To know what language version you're currently using, put `#error version` (case sensitive) in your code. This makes the compiler report a compiler error, CS8304, with a message containing the compiler version being used and the current selected language version. See [#error \(C# Reference\)](#) for more information.

Edit the project file

You can set the language version in your project file. For example, if you explicitly want access to preview features, add an element like this:

```
<PropertyGroup>
  <LangVersion>preview</LangVersion>
</PropertyGroup>
```

The value `preview` uses the latest available preview C# language version that your compiler supports.

Configure multiple projects

To configure multiple projects, you can create a **Directory.Build.props** file that contains the `<LangVersion>` element. You typically do that in your solution directory. Add the following to a **Directory.Build.props** file in your solution directory:

```
<Project>
  <PropertyGroup>
    <LangVersion>preview</LangVersion>
  </PropertyGroup>
</Project>
```

Builds in all subdirectories of the directory containing that file will use the preview C# version. For more information, see [Customize your build](#).

C# language version reference

The following table shows all current C# language versions. Your compiler may not necessarily understand every value if it's older. If you install the latest .NET SDK, then you have access to everything listed.

VALUE	MEANING
<code>preview</code>	The compiler accepts all valid language syntax from the latest preview version.
<code>latest</code>	The compiler accepts syntax from the latest released version of the compiler (including minor version).
<code>latestMajor</code> (<code>default</code>)	The compiler accepts syntax from the latest released major version of the compiler.
<code>10.0</code>	The compiler accepts only syntax that is included in C# 10 or lower.
<code>9.0</code>	The compiler accepts only syntax that is included in C# 9 or lower.
<code>8.0</code>	The compiler accepts only syntax that is included in C# 8.0 or lower.
<code>7.3</code>	The compiler accepts only syntax that is included in C# 7.3 or lower.
<code>7.2</code>	The compiler accepts only syntax that is included in C# 7.2 or lower.
<code>7.1</code>	The compiler accepts only syntax that is included in C# 7.1 or lower.
<code>7</code>	The compiler accepts only syntax that is included in C# 7.0 or lower.
<code>6</code>	The compiler accepts only syntax that is included in C# 6.0 or lower.
<code>5</code>	The compiler accepts only syntax that is included in C# 5.0 or lower.
<code>4</code>	The compiler accepts only syntax that is included in C# 4.0 or lower.
<code>3</code>	The compiler accepts only syntax that is included in C# 3.0 or lower.
<code>ISO-2</code> (or <code>2</code>)	The compiler accepts only syntax that is included in ISO/IEC 23270:2006 C# (2.0).
<code>ISO-1</code> (or <code>1</code>)	The compiler accepts only syntax that is included in ISO/IEC 23270:2003 C# (1.0/1.2).

Value types (C# reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

Value types and *reference types* are the two main categories of C# types. A variable of a value type contains an instance of the type. This differs from a variable of a reference type, which contains a reference to an instance of the type. By default, on [assignment](#), passing an argument to a method, and returning a method result, variable values are copied. In the case of value-type variables, the corresponding type instances are copied. The following example demonstrates that behavior:

```
using System;

public struct MutablePoint
{
    public int X;
    public int Y;

    public MutablePoint(int x, int y) => (X, Y) = (x, y);

    public override string ToString() => $"({X}, {Y})";
}

public class Program
{
    public static void Main()
    {
        var p1 = new MutablePoint(1, 2);
        var p2 = p1;
        p2.Y = 200;
        Console.WriteLine($"{nameof(p1)} after {nameof(p2)} is modified: {p1}");
        Console.WriteLine($"{nameof(p2)}: {p2}");

        MutateAndDisplay(p2);
        Console.WriteLine($"{nameof(p2)} after passing to a method: {p2}");
    }

    private static void MutateAndDisplay(MutablePoint p)
    {
        p.X = 100;
        Console.WriteLine($"Point mutated in a method: {p}");
    }
}

// Expected output:
// p1 after p2 is modified: (1, 2)
// p2: (1, 200)
// Point mutated in a method: (100, 200)
// p2 after passing to a method: (1, 200)
```

As the preceding example shows, operations on a value-type variable affect only that instance of the value type, stored in the variable.

If a value type contains a data member of a reference type, only the reference to the instance of the reference type is copied when a value-type instance is copied. Both the copy and original value-type instance have access to the same reference-type instance. The following example demonstrates that behavior:

```

using System;
using System.Collections.Generic;

public struct TaggedInteger
{
    public int Number;
    private List<string> tags;

    public TaggedInteger(int n)
    {
        Number = n;
        tags = new List<string>();
    }

    public void AddTag(string tag) => tags.Add(tag);

    public override string ToString() => $"{Number} [{string.Join(", ", tags)}]";
}

public class Program
{
    public static void Main()
    {
        var n1 = new TaggedInteger(0);
        n1.AddTag("A");
        Console.WriteLine(n1); // output: 0 [A]

        var n2 = n1;
        n2.Number = 7;
        n2.AddTag("B");

        Console.WriteLine(n1); // output: 0 [A, B]
        Console.WriteLine(n2); // output: 7 [A, B]
    }
}

```

NOTE

To make your code less error-prone and more robust, define and use immutable value types. This article uses mutable value types only for demonstration purposes.

Kinds of value types and type constraints

A value type can be one of the two following kinds:

- a [structure type](#), which encapsulates data and related functionality
- an [enumeration type](#), which is defined by a set of named constants and represents a choice or a combination of choices

A [nullable value type](#) `T?` represents all values of its underlying value type `T` and an additional [null](#) value. You cannot assign `null` to a variable of a value type, unless it's a nullable value type.

You can use the [struct constraint](#) to specify that a type parameter is a non-nullable value type. Both structure and enumeration types satisfy the `struct` constraint. Beginning with C# 7.3, you can use `System.Enum` in a base class constraint (that is known as the [enum constraint](#)) to specify that a type parameter is an enumeration type.

Built-in value types

C# provides the following built-in value types, also known as *simple types*.

- [Integral numeric types](#)
- [Floating-point numeric types](#)
- `bool` that represents a Boolean value
- `char` that represents a Unicode UTF-16 character

All simple types are structure types and differ from other structure types in that they permit certain additional operations:

- You can use literals to provide a value of a simple type. For example, `'A'` is a literal of the type `char` and `2001` is a literal of the type `int`.
- You can declare constants of the simple types with the `const` keyword. It's not possible to have constants of other structure types.
- Constant expressions, whose operands are all constants of the simple types, are evaluated at compile time.

Beginning with C# 7.0, C# supports [value tuples](#). A value tuple is a value type, but not a simple type.

C# language specification

For more information, see the following sections of the [C# language specification](#):

- [Value types](#)
- [Simple types](#)
- [Variables](#)

See also

- [C# reference](#)
- [System.ValueType](#)
- [Reference types](#)

Integral numeric types (C# reference)

12/28/2021 • 4 minutes to read • [Edit Online](#)

The *integral numeric types* represent integer numbers. All integral numeric types are [value types](#). They are also [simple types](#) and can be initialized with [literals](#). All integral numeric types support [arithmetic](#), [bitwise logical](#), [comparison](#), and [equality](#) operators.

Characteristics of the integral types

C# supports the following predefined integral types:

C# TYPE/KEYWORD	RANGE	SIZE	.NET TYPE
<code>sbyte</code>	-128 to 127	Signed 8-bit integer	System.SByte
<code>byte</code>	0 to 255	Unsigned 8-bit integer	System.Byte
<code>short</code>	-32,768 to 32,767	Signed 16-bit integer	System.Int16
<code>ushort</code>	0 to 65,535	Unsigned 16-bit integer	System.UInt16
<code>int</code>	-2,147,483,648 to 2,147,483,647	Signed 32-bit integer	System.Int32
<code>uint</code>	0 to 4,294,967,295	Unsigned 32-bit integer	System.UInt32
<code>long</code>	-9,223,372,036,854,775,808 to 9,223,372,036,854,775,807	Signed 64-bit integer	System.Int64
<code>ulong</code>	0 to 18,446,744,073,709,551,615	Unsigned 64-bit integer	System.UInt64
<code>nint</code>	Depends on platform	Signed 32-bit or 64-bit integer	System.IntPtr
<code>nuint</code>	Depends on platform	Unsigned 32-bit or 64-bit integer	System.UIntPtr

In all of the table rows except the last two, each C# type keyword from the leftmost column is an alias for the corresponding .NET type. The keyword and .NET type name are interchangeable. For example, the following declarations declare variables of the same type:

```
int a = 123;  
System.Int32 b = 123;
```

The `nint` and `nuint` types in the last two rows of the table are native-sized integers. They are represented internally by the indicated .NET types, but in each case the keyword and the .NET type are not interchangeable.

The compiler provides operations and conversions for `nint` and `nuint` as integer types that it doesn't provide for the pointer types `System.IntPtr` and `System.UIntPtr`. For more information, see [nint and nuint types](#).

The default value of each integral type is zero, `0`. Each of the integral types except the native-sized types has `MinValue` and `MaxValue` constants that provide the minimum and maximum value of that type.

Use the [System.Numerics.BigInteger](#) structure to represent a signed integer with no upper or lower bounds.

Integer literals

Integer literals can be

- *decimal*: without any prefix
- *hexadecimal*: with the `0x` or `0X` prefix
- *binary*: with the `0b` or `0B` prefix (available in C# 7.0 and later)

The following code demonstrates an example of each:

```
var decimalLiteral = 42;
var hexLiteral = 0x2A;
var binaryLiteral = 0b_0010_1010;
```

The preceding example also shows the use of `_` as a *digit separator*, which is supported starting with C# 7.0. You can use the digit separator with all kinds of numeric literals.

The type of an integer literal is determined by its suffix as follows:

- If the literal has no suffix, its type is the first of the following types in which its value can be represented:

`int`, `uint`, `long`, `ulong`.

NOTE

Literals are interpreted as positive values. For example, the literal `0xFF_FF_FF_FF` represents the number `4294967295` of the `uint` type, though it has the same bit representation as the number `-1` of the `int` type. If you need a value of a certain type, cast a literal to that type. Use the `unchecked` operator, if a literal value cannot be represented in the target type. For example, `unchecked((int)0xFF_FF_FF_FF)` produces `-1`.

- If the literal is suffixed by `U` or `u`, its type is the first of the following types in which its value can be represented: `uint`, `ulong`.
- If the literal is suffixed by `L` or `l`, its type is the first of the following types in which its value can be represented: `long`, `ulong`.

NOTE

You can use the lowercase letter `l` as a suffix. However, this generates a compiler warning because the letter `l` can be confused with the digit `1`. Use `L` for clarity.

- If the literal is suffixed by `UL`, `Ul`, `uL`, `ul`, `LU`, `Lu`, `lU`, or `lu`, its type is `ulong`.

If the value represented by an integer literal exceeds `UInt64.MaxValue`, a compiler error [CS1021](#) occurs.

If the determined type of an integer literal is `int` and the value represented by the literal is within the range of the destination type, the value can be implicitly converted to `sbyte`, `byte`, `short`, `ushort`, `uint`, `ulong`, `nint` or `nuint`:

```
byte a = 17;
byte b = 300;    // CS0031: Constant value '300' cannot be converted to a 'byte'
```

As the preceding example shows, if the literal's value is not within the range of the destination type, a compiler error [CS0031](#) occurs.

You can also use a cast to convert the value represented by an integer literal to the type other than the determined type of the literal:

```
var signedByte = (sbyte)42;
var longVariable = (long)42;
```

Conversions

You can convert any integral numeric type to any other integral numeric type. If the destination type can store all values of the source type, the conversion is implicit. Otherwise, you need to use a [cast expression](#) to perform an explicit conversion. For more information, see [Built-in numeric conversions](#).

C# language specification

For more information, see the following sections of the [C# language specification](#):

- [Integral types](#)
- [Integer literals](#)

- [Numerics in .NET](#)

nint and nuint types (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Starting in C# 9.0, you can use the `nint` and `nuint` keywords to define *native-sized integers*. These are 32-bit integers when running in a 32-bit process, or 64-bit integers when running in a 64-bit process. They can be used for interop scenarios, low-level libraries, and to optimize performance in scenarios where integer math is used extensively.

The native-sized integer types are represented internally as the .NET types `System.IntPtr` and `System.UIntPtr`. Unlike other numeric types, the keywords are not simply aliases for the types. The following statements are not equivalent:

```
nint a = 1;
System.IntPtr a = 1;
```

The compiler provides operations and conversions for `nint` and `nuint` that are appropriate for integer types.

Run-time native integer size

To get the size of a native-sized integer at run time, you can use `sizeof()`. However, the code must be compiled in an unsafe context. For example:

```
Console.WriteLine($"size of nint = {sizeof(nint)}");
Console.WriteLine($"size of nuint = {sizeof(nuint)}");

// output when run in a 64-bit process
//size of nint = 8
//size of nuint = 8

// output when run in a 32-bit process
//size of nint = 4
//size of nuint = 4
```

You can also get the equivalent value from the static `IntPtr.Size` and `UIntPtr.Size` properties.

MinValue and MaxValue

To get the minimum and maximum values of native-sized integers at run time, use `MinValue` and `MaxValue` as static properties with the `nint` and `nuint` keywords, as in the following example:

```

Console.WriteLine($"nint.MinValue = {nint.MinValue}");
Console.WriteLine($"nint.MaxValue = {nint.MaxValue}");
Console.WriteLine($"nuint.MinValue = {nuint.MinValue}");
Console.WriteLine($"nuint.MaxValue = {nuint.MaxValue}");

// output when run in a 64-bit process
//nint.MinValue = -9223372036854775808
//nint.MaxValue = 9223372036854775807
//nuint.MinValue = 0
//nuint.MaxValue = 18446744073709551615

// output when run in a 32-bit process
//nint.MinValue = -2147483648
//nint.MaxValue = 2147483647
//nuint.MinValue = 0
//nuint.MaxValue = 4294967295

```

Constants

You can use constant values in the following ranges:

- For `nint`: [Int32.MinValue](#) to [Int32.MaxValue](#).
- For `nuint`: [UInt32.MinValue](#) to [UInt32.MaxValue](#).

Conversions

The compiler provides implicit and explicit conversions to other numeric types. For more information, see [Built-in numeric conversions](#).

Literals

There's no direct syntax for native-sized integer literals. There's no suffix to indicate that a literal is a native-sized integer, such as `L` to indicate a `long`. You can use implicit or explicit casts of other integer values instead. For example:

```

nint a = 42
nint a = (nint)42;

```

Unsupported IntPtr/UIntPtr members

The following members of [IntPtr](#) and [UIntPtr](#) aren't supported for `nint` and `nuint` types:

- Parameterized constructors
- [Add\(IntPtr, Int32\)](#)
- [CompareTo](#)
- [Size](#) - Use [sizeof\(\)](#) instead. Although `nint.Size` isn't supported, you can use `IntPtr.Size` to get an equivalent value.
- [Subtract\(IntPtr, Int32\)](#)
- [ToInt32](#)
- [ToInt64](#)
- [ToPointer](#)
- [Zero](#) - Use 0 instead.

C# language specification

For more information, see the [C# language specification](#) and the [Native-sized integers](#) section of the C# 9.0 feature proposal notes.

Floating-point numeric types (C# reference)

12/28/2021 • 4 minutes to read • [Edit Online](#)

The *floating-point numeric types* represent real numbers. All floating-point numeric types are [value types](#). They are also [simple types](#) and can be initialized with [literals](#). All floating-point numeric types support [arithmetic](#), [comparison](#), and [equality](#) operators.

Characteristics of the floating-point types

C# supports the following predefined floating-point types:

C# TYPE/KEYWORD	APPROXIMATE RANGE	PRECISION	SIZE	.NET TYPE
<code>float</code>	$\pm 1.5 \times 10^{-45}$ to $\pm 3.4 \times 10^{38}$	~6-9 digits	4 bytes	System.Single
<code>double</code>	$\pm 5.0 \times 10^{-324}$ to $\pm 1.7 \times 10^{308}$	~15-17 digits	8 bytes	System.Double
<code>decimal</code>	$\pm 1.0 \times 10^{-28}$ to $\pm 7.9228 \times 10^{28}$	28-29 digits	16 bytes	System.Decimal

In the preceding table, each C# type keyword from the leftmost column is an alias for the corresponding .NET type. They are interchangeable. For example, the following declarations declare variables of the same type:

```
double a = 12.3;
System.Double b = 12.3;
```

The default value of each floating-point type is zero, `0`. Each of the floating-point types has the `MinValue` and `MaxValue` constants that provide the minimum and maximum finite value of that type. The `float` and `double` types also provide constants that represent not-a-number and infinity values. For example, the `double` type provides the following constants: [Double.NaN](#), [Double.NegativeInfinity](#), and [Double.PositiveInfinity](#).

The `decimal` type is appropriate when the required degree of precision is determined by the number of digits to the right of the decimal point. Such numbers are commonly used in financial applications, for currency amounts (for example, \$1.00), interest rates (for example, 2.625%), and so forth. Even numbers that are precise to only one decimal digit are handled more accurately by the `decimal` type: 0.1, for example, can be exactly represented by a `decimal` instance, while there's no `double` or `float` instance that exactly represents 0.1. Because of this difference in numeric types, unexpected rounding errors can occur in arithmetic calculations when you use `double` or `float` for decimal data. You can use `double` instead of `decimal` when optimizing performance is more important than ensuring accuracy. However, any difference in performance would go unnoticed by all but the most calculation-intensive applications. Another possible reason to avoid `decimal` is to minimize storage requirements. For example, [ML.NET](#) uses `float` because the difference between 4 bytes and 16 bytes adds up for very large data sets. For more information, see [System.Decimal](#).

You can mix [integral](#) types and the `float` and `double` types in an expression. In this case, integral types are implicitly converted to one of the floating-point types and, if necessary, the `float` type is implicitly converted to `double`. The expression is evaluated as follows:

- If there is `double` type in the expression, the expression evaluates to `double`, or to `bool` in relational and equality comparisons.
- If there is no `double` type in the expression, the expression evaluates to `float`, or to `bool` in relational and equality comparisons.

You can also mix integral types and the `decimal` type in an expression. In this case, integral types are implicitly converted to the `decimal` type and the expression evaluates to `decimal`, or to `bool` in relational and equality comparisons.

You cannot mix the `decimal` type with the `float` and `double` types in an expression. In this case, if you want to perform arithmetic, comparison, or equality operations, you must explicitly convert the operands either from or to the `decimal` type, as the following example shows:

```
double a = 1.0;
decimal b = 2.1m;
Console.WriteLine(a + (double)b);
Console.WriteLine((decimal)a + b);
```

You can use either [standard numeric format strings](#) or [custom numeric format strings](#) to format a floating-point value.

Real literals

The type of a real literal is determined by its suffix as follows:

- The literal without suffix or with the `d` or `D` suffix is of type `double`
- The literal with the `f` or `F` suffix is of type `float`
- The literal with the `m` or `M` suffix is of type `decimal`

The following code demonstrates an example of each:

```
double d = 3D;
d = 4d;
d = 3.934_001;

float f = 3_000.5F;
f = 5.4f;

decimal myMoney = 3_000.5m;
myMoney = 400.75M;
```

The preceding example also shows the use of `_` as a *digit separator*, which is supported starting with C# 7.0. You can use the digit separator with all kinds of numeric literals.

You can also use scientific notation, that is, specify an exponent part of a real literal, as the following example shows:

```
double d = 0.42e2;
Console.WriteLine(d); // output 42

float f = 134.45E-2f;
Console.WriteLine(f); // output: 1.3445

decimal m = 1.5E6m;
Console.WriteLine(m); // output: 1500000
```

Conversions

There is only one implicit conversion between floating-point numeric types: from `float` to `double`. However, you can convert any floating-point type to any other floating-point type with the [explicit cast](#). For more information, see [Built-in numeric conversions](#).

C# language specification

For more information, see the following sections of the [C# language specification](#):

- [Floating-point types](#)
- [The decimal type](#)
- [Real literals](#)

- [System.Numerics.Complex](#)

Built-in numeric conversions (C# reference)

12/28/2021 • 4 minutes to read • [Edit Online](#)

C# provides a set of [integral](#) and [floating-point](#) numeric types. There exists a conversion between any two numeric types, either implicit or explicit. You must use a [cast expression](#) to perform an explicit conversion.

Implicit numeric conversions

The following table shows the predefined implicit conversions between the built-in numeric types:

FROM	TO
sbyte	short , int , long , float , double , decimal , OR nint
byte	short , ushort , int , uint , long , ulong , float , double , decimal , nint , OR nuint
short	int , long , float , double , OR decimal , OR nint
ushort	int , uint , long , ulong , float , double , OR decimal , nint , OR nuint
int	long , float , double , OR decimal , nint
uint	long , ulong , float , double , OR decimal , OR nuint
long	float , double , OR decimal
ulong	float , double , OR decimal
float	double
nint	long , float , double , OR decimal
nuint	ulong , float , double , OR decimal

NOTE

The implicit conversions from [int](#), [uint](#), [long](#), [ulong](#), [nint](#), OR [nuint](#) to [float](#) and from [long](#), [ulong](#), [nint](#), OR [nuint](#) to [double](#) may cause a loss of precision, but never a loss of an order of magnitude. The other implicit numeric conversions never lose any information.

Also note that

- Any [integral numeric type](#) is implicitly convertible to any [floating-point numeric type](#).
- There are no implicit conversions to the [byte](#) and [sbyte](#) types. There are no implicit conversions from the [double](#) and [decimal](#) types.

- There are no implicit conversions between the `decimal` type and the `float` or `double` types.
- A value of a constant expression of type `int` (for example, a value represented by an integer literal) can be implicitly converted to `sbyte`, `byte`, `short`, `ushort`, `uint`, `ulong`, `nint`, or `nuint`, if it's within the range of the destination type:

```
byte a = 13;
byte b = 300; // CS0031: Constant value '300' cannot be converted to a 'byte'
```

As the preceding example shows, if the constant value is not within the range of the destination type, a compiler error [CS0031](#) occurs.

Explicit numeric conversions

The following table shows the predefined explicit conversions between the built-in numeric types for which there is no [implicit conversion](#):

FROM	TO
sbyte	<code>byte</code> , <code>ushort</code> , <code>uint</code> , or <code>ulong</code> , or <code>nuint</code>
byte	<code>sbyte</code>
short	<code>sbyte</code> , <code>byte</code> , <code>ushort</code> , <code>uint</code> , <code>ulong</code> , or <code>nuint</code>
ushort	<code>sbyte</code> , <code>byte</code> , or <code>short</code>
int	<code>sbyte</code> , <code>byte</code> , <code>short</code> , <code>ushort</code> , <code>uint</code> , <code>ulong</code> , or <code>nuint</code>
uint	<code>sbyte</code> , <code>byte</code> , <code>short</code> , <code>ushort</code> , or <code>int</code>
long	<code>sbyte</code> , <code>byte</code> , <code>short</code> , <code>ushort</code> , <code>int</code> , <code>uint</code> , <code>ulong</code> , <code>nint</code> , or <code>nuint</code>
ulong	<code>sbyte</code> , <code>byte</code> , <code>short</code> , <code>ushort</code> , <code>int</code> , <code>uint</code> , <code>long</code> , <code>nint</code> , or <code>nuint</code>
float	<code>sbyte</code> , <code>byte</code> , <code>short</code> , <code>ushort</code> , <code>int</code> , <code>uint</code> , <code>long</code> , <code>ulong</code> , <code>decimal</code> , <code>nint</code> , or <code>nuint</code>
double	<code>sbyte</code> , <code>byte</code> , <code>short</code> , <code>ushort</code> , <code>int</code> , <code>uint</code> , <code>long</code> , <code>ulong</code> , <code>float</code> , <code>decimal</code> , <code>nint</code> , or <code>nuint</code>
decimal	<code>sbyte</code> , <code>byte</code> , <code>short</code> , <code>ushort</code> , <code>int</code> , <code>uint</code> , <code>long</code> , <code>ulong</code> , <code>float</code> , <code>double</code> , <code>nint</code> , or <code>nuint</code>
nint	<code>sbyte</code> , <code>byte</code> , <code>short</code> , <code>ushort</code> , <code>int</code> , <code>uint</code> , <code>ulong</code> , or <code>nuint</code>
nuint	<code>sbyte</code> , <code>byte</code> , <code>short</code> , <code>ushort</code> , <code>int</code> , <code>uint</code> , <code>long</code> , or <code>nint</code>

NOTE

An explicit numeric conversion might result in data loss or throw an exception, typically an [OverflowException](#).

Also note that

- When you convert a value of an integral type to another integral type, the result depends on the overflow [checking context](#). In a checked context, the conversion succeeds if the source value is within the range of the destination type. Otherwise, an [OverflowException](#) is thrown. In an unchecked context, the conversion always succeeds, and proceeds as follows:
 - If the source type is larger than the destination type, then the source value is truncated by discarding its "extra" most significant bits. The result is then treated as a value of the destination type.
 - If the source type is smaller than the destination type, then the source value is either sign-extended or zero-extended so that it's of the same size as the destination type. Sign-extension is used if the source type is signed; zero-extension is used if the source type is unsigned. The result is then treated as a value of the destination type.
 - If the source type is the same size as the destination type, then the source value is treated as a value of the destination type.
- When you convert a `decimal` value to an integral type, this value is rounded towards zero to the nearest integral value. If the resulting integral value is outside the range of the destination type, an [OverflowException](#) is thrown.
- When you convert a `double` or `float` value to an integral type, this value is rounded towards zero to the nearest integral value. If the resulting integral value is outside the range of the destination type, the result depends on the overflow [checking context](#). In a checked context, an [OverflowException](#) is thrown, while in an unchecked context, the result is an unspecified value of the destination type.
- When you convert `double` to `float`, the `double` value is rounded to the nearest `float` value. If the `double` value is too small or too large to fit into the `float` type, the result is zero or infinity.
- When you convert `float` or `double` to `decimal`, the source value is converted to `decimal` representation and rounded to the nearest number after the 28th decimal place if required. Depending on the value of the source value, one of the following results may occur:
 - If the source value is too small to be represented as a `decimal`, the result becomes zero.
 - If the source value is NaN (not a number), infinity, or too large to be represented as a `decimal`, an [OverflowException](#) is thrown.
- When you convert `decimal` to `float` or `double`, the source value is rounded to the nearest `float` or `double` value, respectively.

C# language specification

For more information, see the following sections of the [C# language specification](#):

- [Implicit numeric conversions](#)
- [Explicit numeric conversions](#)

See also

- [C# reference](#)
- [Casting and type conversions](#)

bool (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `bool` type keyword is an alias for the .NET [System.Boolean](#) structure type that represents a Boolean value, which can be either `true` or `false`.

To perform logical operations with values of the `bool` type, use [Boolean logical](#) operators. The `bool` type is the result type of [comparison](#) and [equality](#) operators. A `bool` expression can be a controlling conditional expression in the [if](#), [do](#), [while](#), and [for](#) statements and in the [conditional operator](#) `?:`.

The default value of the `bool` type is `false`.

Literals

You can use the `true` and `false` literals to initialize a `bool` variable or to pass a `bool` value:

```
bool check = true;
Console.WriteLine(check ? "Checked" : "Not checked"); // output: Checked

Console.WriteLine(false ? "Checked" : "Not checked"); // output: Not checked
```

Three-valued Boolean logic

Use the nullable `bool?` type, if you need to support the three-valued logic, for example, when you work with databases that support a three-valued Boolean type. For the `bool?` operands, the predefined `&` and `|` operators support the three-valued logic. For more information, see the [Nullable Boolean logical operators](#) section of the [Boolean logical operators](#) article.

For more information about nullable value types, see [Nullable value types](#).

Conversions

C# provides only two conversions that involve the `bool` type. Those are an implicit conversion to the corresponding nullable `bool?` type and an explicit conversion from the `bool?` type. However, .NET provides additional methods that you can use to convert to or from the `bool` type. For more information, see the [Converting to and from Boolean values](#) section of the [System.Boolean](#) API reference page.

C# language specification

For more information, see [The bool type](#) section of the [C# language specification](#).

See also

- [C# reference](#)
- [Value types](#)
- [true and false operators](#)

char (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `char` type keyword is an alias for the .NET [System.Char](#) structure type that represents a Unicode UTF-16 character.

TYPE	RANGE	SIZE	.NET TYPE
<code>char</code>	U+0000 to U+FFFF	16 bit	System.Char

The default value of the `char` type is `\0`, that is, U+0000.

The `char` type supports [comparison](#), [equality](#), [increment](#), and [decrement](#) operators. Moreover, for `char` operands, [arithmetic](#) and [bitwise logical](#) operators perform an operation on the corresponding character codes and produce the result of the `int` type.

The [string](#) type represents text as a sequence of `char` values.

Literals

You can specify a `char` value with:

- a character literal.
- a Unicode escape sequence, which is `\u` followed by the four-symbol hexadecimal representation of a character code.
- a hexadecimal escape sequence, which is `\x` followed by the hexadecimal representation of a character code.

```
var chars = new[]
{
    'j',
    '\u006A',
    '\x006A',
    (char)106,
};
Console.WriteLine(string.Join(" ", chars)); // output: j j j j
```

As the preceding example shows, you can also cast the value of a character code into the corresponding `char` value.

NOTE

In the case of a Unicode escape sequence, you must specify all four hexadecimal digits. That is, `\u006A` is a valid escape sequence, while `\u06A` and `\u6A` are not valid.

In the case of a hexadecimal escape sequence, you can omit the leading zeros. That is, the `\x006A`, `\x06A`, and `\x6A` escape sequences are valid and correspond to the same character.

Conversions

The `char` type is implicitly convertible to the following [integral](#) types: `ushort`, `int`, `uint`, `long`, and `ulong`.

It's also implicitly convertible to the built-in [floating-point](#) numeric types: `float`, `double`, and `decimal`. It's explicitly convertible to `sbyte`, `byte`, and `short` integral types.

There are no implicit conversions from other types to the `char` type. However, any [integral](#) or [floating-point](#) numeric type is explicitly convertible to `char`.

C# language specification

For more information, see the [Integral types](#) section of the [C# language specification](#).

- [Strings](#)
- [System.Text.Rune](#)
- [Character encoding in .NET](#)

Enumeration types (C# reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

An *enumeration type* (or *enum type*) is a [value type](#) defined by a set of named constants of the underlying [integral numeric](#) type. To define an enumeration type, use the `enum` keyword and specify the names of *enum members*.

```
enum Season
{
    Spring,
    Summer,
    Autumn,
    Winter
}
```

By default, the associated constant values of enum members are of type `int`; they start with zero and increase by one following the definition text order. You can explicitly specify any other [integral numeric](#) type as an underlying type of an enumeration type. You can also explicitly specify the associated constant values, as the following example shows:

```
enum ErrorCode : ushort
{
    None = 0,
    Unknown = 1,
    ConnectionLost = 100,
    OutlierReading = 200
}
```

You cannot define a method inside the definition of an enumeration type. To add functionality to an enumeration type, create an [extension method](#).

The default value of an enumeration type `E` is the value produced by expression `(E)0`, even if zero doesn't have the corresponding enum member.

You use an enumeration type to represent a choice from a set of mutually exclusive values or a combination of choices. To represent a combination of choices, define an enumeration type as bit flags.

Enumeration types as bit flags

If you want an enumeration type to represent a combination of choices, define enum members for those choices such that an individual choice is a bit field. That is, the associated values of those enum members should be the powers of two. Then, you can use the [bitwise logical operators](#) `|` or `&` to combine choices or intersect combinations of choices, respectively. To indicate that an enumeration type declares bit fields, apply the [Flags](#) attribute to it. As the following example shows, you can also include some typical combinations in the definition of an enumeration type.

```

[Flags]
public enum Days
{
    None      = 0b_0000_0000, // 0
    Monday    = 0b_0000_0001, // 1
    Tuesday   = 0b_0000_0010, // 2
    Wednesday = 0b_0000_0100, // 4
    Thursday  = 0b_0000_1000, // 8
    Friday    = 0b_0001_0000, // 16
    Saturday  = 0b_0010_0000, // 32
    Sunday    = 0b_0100_0000, // 64
    Weekend   = Saturday | Sunday
}

public class FlagsEnumExample
{
    public static void Main()
    {
        Days meetingDays = Days.Monday | Days.Wednesday | Days.Friday;
        Console.WriteLine(meetingDays);
        // Output:
        // Monday, Wednesday, Friday

        Days workingFromHomeDays = Days.Thursday | Days.Friday;
        Console.WriteLine($"Join a meeting by phone on {meetingDays & workingFromHomeDays}");
        // Output:
        // Join a meeting by phone on Friday

        bool isMeetingOnTuesday = (meetingDays & Days.Tuesday) == Days.Tuesday;
        Console.WriteLine($"Is there a meeting on Tuesday: {isMeetingOnTuesday}");
        // Output:
        // Is there a meeting on Tuesday: False

        var a = (Days)37;
        Console.WriteLine(a);
        // Output:
        // Monday, Wednesday, Saturday
    }
}

```

For more information and examples, see the [System.FlagsAttribute](#) API reference page and the [Non-exclusive members and the Flags attribute](#) section of the [System.Enum](#) API reference page.

The System.Enum type and enum constraint

The [System.Enum](#) type is the abstract base class of all enumeration types. It provides a number of methods to get information about an enumeration type and its values. For more information and examples, see the [System.Enum](#) API reference page.

Beginning with C# 7.3, you can use `System.Enum` in a base class constraint (that is known as the [enum constraint](#)) to specify that a type parameter is an enumeration type. Any enumeration type also satisfies the `struct` constraint, which is used to specify that a type parameter is a non-nullable value type.

Conversions

For any enumeration type, there exist explicit conversions between the enumeration type and its underlying integral type. If you [cast](#) an enum value to its underlying type, the result is the associated integral value of an enum member.

```

public enum Season
{
    Spring,
    Summer,
    Autumn,
    Winter
}

public class EnumConversionExample
{
    public static void Main()
    {
        Season a = Season.Autumn;
        Console.WriteLine($"Integral value of {a} is {(int)a}"); // output: Integral value of Autumn is 2

        var b = (Season)1;
        Console.WriteLine(b); // output: Summer

        var c = (Season)4;
        Console.WriteLine(c); // output: 4
    }
}

```

Use the [Enum.IsDefined](#) method to determine whether an enumeration type contains an enum member with the certain associated value.

For any enumeration type, there exist [boxing and unboxing](#) conversions to and from the [System.Enum](#) type, respectively.

C# language specification

For more information, see the following sections of the [C# language specification](#):

Structure types (C# reference)

12/28/2021 • 11 minutes to read • [Edit Online](#)

A *structure type* (or *struct type*) is a [value type](#) that can encapsulate data and related functionality. You use the `struct` keyword to define a structure type:

```
public struct Coords
{
    public Coords(double x, double y)
    {
        X = x;
        Y = y;
    }

    public double X { get; }
    public double Y { get; }

    public override string ToString() => $"({X}, {Y})";
}
```

Structure types have *value semantics*. That is, a variable of a structure type contains an instance of the type. By default, variable values are copied on assignment, passing an argument to a method, and returning a method result. In the case of a structure-type variable, an instance of the type is copied. For more information, see [Value types](#).

Typically, you use structure types to design small data-centric types that provide little or no behavior. For example, .NET uses structure types to represent a number (both [integer](#) and [real](#)), a [Boolean value](#), a [Unicode character](#), a [time instance](#). If you're focused on the behavior of a type, consider defining a [class](#). Class types have *reference semantics*. That is, a variable of a class type contains a reference to an instance of the type, not the instance itself.

Because structure types have value semantics, we recommend you to define *immutable* structure types.

`readonly` `struct`

Beginning with C# 7.2, you use the `readonly` modifier to declare that a structure type is immutable. All data members of a `readonly` struct must be read-only as follows:

- Any field declaration must have the `readonly` modifier
- Any property, including auto-implemented ones, must be read-only. In C# 9.0 and later, a property may have an `init` accessor.

That guarantees that no member of a `readonly` struct modifies the state of the struct. In C# 8.0 and later, that means that other instance members except constructors are implicitly `readonly`.

NOTE

In a `readonly` struct, a data member of a mutable reference type still can mutate its own state. For example, you can't replace a `List<T>` instance, but you can add new elements to it.

The following code defines a `readonly` struct with init-only property setters, available in C# 9.0 and later:

```
public readonly struct Coords
{
    public Coords(double x, double y)
    {
        X = x;
        Y = y;
    }

    public double X { get; init; }
    public double Y { get; init; }

    public override string ToString() => $"({X}, {Y})";
}
```

readonly instance members

Beginning with C# 8.0, you can also use the `readonly` modifier to declare that an instance member doesn't modify the state of a struct. If you can't declare the whole structure type as `readonly`, use the `readonly` modifier to mark the instance members that don't modify the state of the struct.

Within a `readonly` instance member, you can't assign to structure's instance fields. However, a `readonly` member can call a non-`readonly` member. In that case the compiler creates a copy of the structure instance and calls the non-`readonly` member on that copy. As a result, the original structure instance is not modified.

Typically, you apply the `readonly` modifier to the following kinds of instance members:

- methods:

```
public readonly double Sum()
{
    return X + Y;
}
```

You can also apply the `readonly` modifier to methods that override methods declared in [System.Object](#):

```
public readonly override string ToString() => $"({X}, {Y})";
```

- properties and indexers:

```
private int counter;
public int Counter
{
    readonly get => counter;
    set => counter = value;
}
```

If you need to apply the `readonly` modifier to both accessors of a property or indexer, apply it in the declaration of the property or indexer.

NOTE

The compiler declares a `get` accessor of an [auto-implemented property](#) as `readonly`, regardless of presence of the `readonly` modifier in a property declaration.

In C# 9.0 and later, you may apply the `readonly` modifier to a property or indexer with an `init`

accessor:

```
public readonly double X { get; init; }
```

You can't apply the `readonly` modifier to static members of a structure type.

The compiler may make use of the `readonly` modifier for performance optimizations. For more information, see [Write safe and efficient C# code](#).

Nondestructive mutation

Beginning with C# 10, you can use the `with` expression to produce a copy of a structure-type instance with the specified properties and fields modified. You use [object initializer](#) syntax to specify what members to modify and their new values, as the following example shows:

```
public readonly struct Coords
{
    public Coords(double x, double y)
    {
        X = x;
        Y = y;
    }

    public double X { get; init; }
    public double Y { get; init; }

    public override string ToString() => $"({X}, {Y})";
}

public static void Main()
{
    var p1 = new Coords(0, 0);
    Console.WriteLine(p1); // output: (0, 0)

    var p2 = p1 with { X = 3 };
    Console.WriteLine(p2); // output: (3, 0)

    var p3 = p1 with { X = 1, Y = 4 };
    Console.WriteLine(p3); // output: (1, 4)
}
```

Limitations with the design of a structure type

When you design a structure type, you have the same capabilities as with a [class](#) type, with the following exceptions:

- You can't declare a parameterless constructor. Every structure type already provides an implicit parameterless constructor that produces the [default value](#) of the type.

NOTE

Beginning with C# 10, you can declare a parameterless constructor in a structure type. For more information, see the [Parameterless constructors and field initializers](#) section.

- You can't initialize an instance field or property at its declaration. However, you can initialize a [static](#) or [const](#) field or a static property at its declaration.

NOTE

Beginning with C# 10, you can initialize an instance field or property at its declaration. For more information, see the [Parameterless constructors and field initializers](#) section.

- A constructor of a structure type must initialize all instance fields of the type.
- A structure type can't inherit from other class or structure type and it can't be the base of a class. However, a structure type can implement [interfaces](#).
- You can't declare a [finalizer](#) within a structure type.

Parameterless constructors and field initializers

Beginning with C# 10, you can declare a parameterless instance constructor in a structure type, as the following example shows:

```
public readonly struct Measurement
{
    public Measurement()
    {
        Value = double.NaN;
        Description = "Undefined";
    }

    public Measurement(double value, string description)
    {
        Value = value;
        Description = description;
    }

    public double Value { get; init; }
    public string Description { get; init; }

    public override string ToString() => $"{Value} ({Description})";
}

public static void Main()
{
    var m1 = new Measurement();
    Console.WriteLine(m1); // output: NaN (Undefined)

    var m2 = default(Measurement);
    Console.WriteLine(m2); // output: 0 ()

    var ms = new Measurement[2];
    Console.WriteLine(string.Join(", ", ms)); // output: 0 (), 0 ()
}
```

As the preceding example shows, the [default value expression](#) ignores a parameterless constructor and produces the default value of a structure type, which is the value produced by setting all value-type fields to their [default values](#) (the 0-bit pattern) and all reference-type fields to `null`. Structure-type array instantiation also ignores a parameterless constructor and produces an array populated with the default values of a structure type.

Beginning with C# 10, you can also initialize an instance field or property at its declaration, as the following example shows:

```

public readonly struct Measurement
{
    public Measurement(double value)
    {
        Value = value;
    }

    public Measurement(double value, string description)
    {
        Value = value;
        Description = description;
    }

    public double Value { get; init; }
    public string Description { get; init; } = "Ordinary measurement";

    public override string ToString() => $"{Value} ({Description})";
}

public static void Main()
{
    var m1 = new Measurement(5);
    Console.WriteLine(m1); // output: 5 (Ordinary measurement)

    var m2 = new Measurement();
    Console.WriteLine(m2); // output: 0 ()

    var m3 = default(Measurement);
    Console.WriteLine(m3); // output: 0 ()
}

```

If you don't declare a parameterless constructor explicitly, a structure type provides a parameterless constructor whose behavior is as follows:

- If a structure type has explicit instance constructors or has no field initializers, an implicit parameterless constructor produces the default value of a structure type, regardless of field initializers, as the preceding example shows.
- If a structure type has no explicit instance constructors and has field initializers, the compiler synthesizes a public parameterless constructor that performs the specified field initializations, as the following example shows:

```

public struct Coords
{
    public double X = double.NaN;
    public double Y = double.NaN;

    public override string ToString() => $"({X}, {Y})";
}

public static void Main()
{
    var p1 = new Coords();
    Console.WriteLine(p1); // output: (NaN, NaN)

    var p2 = default(Coords);
    Console.WriteLine(p2); // output: (0, 0)

    var ps = new Coords[3];
    Console.WriteLine(string.Join(", ", ps)); // output: (0, 0), (0, 0), (0, 0)
}

```

As the preceding example shows, the default value expression and array instantiation ignore field initializers.

IMPORTANT

When a `struct` includes field initializers, but doesn't include any explicit instance constructors, the synthesized public parameterless constructor performs the specified field initializers. If that `struct` includes an explicit instance constructor, the synthesized parameterless constructor produces the same value as the `default` expression.

For more information, see the [Parameterless struct constructors](#) feature proposal note.

Instantiation of a structure type

In C#, you must initialize a declared variable before it can be used. Because a structure-type variable can't be `null` (unless it's a variable of a [nullable value type](#)), you must instantiate an instance of the corresponding type. There are several ways to do that.

Typically, you instantiate a structure type by calling an appropriate constructor with the `new` operator. Every structure type has at least one constructor. That's an implicit parameterless constructor, which produces the [default value](#) of the type. You can also use a [default value expression](#) to produce the default value of a type.

If all instance fields of a structure type are accessible, you can also instantiate it without the `new` operator. In that case you must initialize all instance fields before the first use of the instance. The following example shows how to do that:

```
public static class StructWithoutNew
{
    public struct Coords
    {
        public double x;
        public double y;
    }

    public static void Main()
    {
        Coords p;
        p.x = 3;
        p.y = 4;
        Console.WriteLine($"{p.x}, {p.y}"); // output: (3, 4)
    }
}
```

In the case of the [built-in value types](#), use the corresponding literals to specify a value of the type.

Passing structure-type variables by reference

When you pass a structure-type variable to a method as an argument or return a structure-type value from a method, the whole instance of a structure type is copied. That can affect the performance of your code in high-performance scenarios that involve large structure types. You can avoid value copying by passing a structure-type variable by reference. Use the `ref`, `out`, or `in` method parameter modifiers to indicate that an argument must be passed by reference. Use [ref returns](#) to return a method result by reference. For more information, see [Write safe and efficient C# code](#).

`ref` struct

Beginning with C# 7.2, you can use the `ref` modifier in the declaration of a structure type. Instances of a `ref` struct type are allocated on the stack and can't escape to the managed heap. To ensure that, the compiler limits the usage of `ref` struct types as follows:

- A `ref` struct can't be the element type of an array.
- A `ref` struct can't be a declared type of a field of a class or a non-`ref` struct.
- A `ref` struct can't implement interfaces.
- A `ref` struct can't be boxed to `System.ValueType` or `System.Object`.
- A `ref` struct can't be a type argument.
- A `ref` struct variable can't be captured by a [lambda expression](#) or a [local function](#).
- A `ref` struct variable can't be used in an `async` method. However, you can use `ref` struct variables in synchronous methods, for example, in those that return `Task` or `Task<TResult>`.
- A `ref` struct variable can't be used in [iterators](#).

Beginning with C# 8.0, you can define a disposable `ref` struct. To do that, ensure that a `ref` struct fits the [disposable pattern](#). That is, it has an instance or extension `Dispose` method, which is accessible, parameterless and has a `void` return type.

Typically, you define a `ref` struct type when you need a type that also includes data members of `ref` struct types:

```
public ref struct CustomRef
{
    public bool IsValid;
    public Span<int> Inputs;
    public Span<int> Outputs;
}
```

To declare a `ref` struct as [readonly](#), combine the `readonly` and `ref` modifiers in the type declaration (the `readonly` modifier must come before the `ref` modifier):

```
public readonly ref struct ConversionRequest
{
    public ConversionRequest(double rate, ReadOnlySpan<double> values)
    {
        Rate = rate;
        Values = values;
    }

    public double Rate { get; }
    public ReadOnlySpan<double> Values { get; }
}
```

In .NET, examples of a `ref` struct are [System.Span<T>](#) and [System.ReadOnlySpan<T>](#).

struct constraint

You also use the `struct` keyword in the [struct constraint](#) to specify that a type parameter is a non-nullable value type. Both structure and [enumeration](#) types satisfy the `struct` constraint.

Conversions

For any structure type (except `ref struct` types), there exist [boxing and unboxing](#) conversions to and from the `System.ValueType` and `System.Object` types. There exist also boxing and unboxing conversions between a structure type and any interface that it implements.

C# language specification

For more information, see the [Structs](#) section of the [C# language specification](#).

For more information about features introduced in C# 7.2 and later, see the following feature proposal notes:

- [Readonly structs](#)
- [Readonly instance members](#)
- [Compile-time safety for ref-like types](#)
- [Parameterless struct constructors](#)
- [Allow `with` expression on structs](#)

Tuple types (C# reference)

12/28/2021 • 8 minutes to read • [Edit Online](#)

Available in C# 7.0 and later, the *tuples* feature provides concise syntax to group multiple data elements in a lightweight data structure. The following example shows how you can declare a tuple variable, initialize it, and access its data members:

```
(double, int) t1 = (4.5, 3);
Console.WriteLine($"Tuple with elements {t1.Item1} and {t1.Item2}.");
// Output:
// Tuple with elements 4.5 and 3.

(double Sum, int Count) t2 = (4.5, 3);
Console.WriteLine($"Sum of {t2.Count} elements is {t2.Sum}.");
// Output:
// Sum of 3 elements is 4.5.
```

As the preceding example shows, to define a tuple type, you specify types of all its data members and, optionally, the [field names](#). You cannot define methods in a tuple type, but you can use the methods provided by .NET, as the following example shows:

```
(double, int) t = (4.5, 3);
Console.WriteLine(t.ToString());
Console.WriteLine($"Hash code of {t} is {t.GetHashCode()}.");
// Output:
// (4.5, 3)
// Hash code of (4.5, 3) is 718460086.
```

Beginning with C# 7.3, tuple types support [equality operators](#) `==` and `!=`. For more information, see the [Tuple equality](#) section.

Tuple types are [value types](#); tuple elements are public fields. That makes tuples *mutable* value types.

NOTE

The tuples feature requires the [System.ValueTuple](#) type and related generic types (for example, [System.ValueTuple<T1,T2>](#)), which are available in .NET Core and .NET Framework 4.7 and later. To use tuples in a project that targets .NET Framework 4.6.2 or earlier, add the NuGet package [System.ValueTuple](#) to the project.

You can define tuples with an arbitrary large number of elements:

```
var t =
(1, 2, 3, 4, 5, 6, 7, 8, 9, 10,
11, 12, 13, 14, 15, 16, 17, 18,
19, 20, 21, 22, 23, 24, 25, 26);
Console.WriteLine(t.Item26); // output: 26
```

Use cases of tuples

One of the most common use cases of tuples is as a method return type. That is, instead of defining [out](#) [method parameters](#), you can group method results in a tuple return type, as the following example shows:

```

var xs = new[] { 4, 7, 9 };
var limits = FindMinMax(xs);
Console.WriteLine($"Limits of [{string.Join(" ", xs)}] are {limits.min} and {limits.max}");
// Output:
// Limits of [4 7 9] are 4 and 9

var ys = new[] { -9, 0, 67, 100 };
var (minimum, maximum) = FindMinMax(ys);
Console.WriteLine($"Limits of [{string.Join(" ", ys)}] are {minimum} and {maximum}");
// Output:
// Limits of [-9 0 67 100] are -9 and 100

(int min, int max) FindMinMax(int[] input)
{
    if (input is null || input.Length == 0)
    {
        throw new ArgumentException("Cannot find minimum and maximum of a null or empty array.");
    }

    var min = int.MaxValue;
    var max = int.MinValue;
    foreach (var i in input)
    {
        if (i < min)
        {
            min = i;
        }
        if (i > max)
        {
            max = i;
        }
    }
    return (min, max);
}

```

As the preceding example shows, you can work with the returned tuple instance directly or [deconstruct](#) it in separate variables.

You can also use tuple types instead of [anonymous types](#); for example, in LINQ queries. For more information, see [Choosing between anonymous and tuple types](#).

Typically, you use tuples to group loosely related data elements. That is usually useful within private and internal utility methods. In the case of public API, consider defining a [class](#) or a [structure](#) type.

Tuple field names

You can explicitly specify the names of tuple fields either in a tuple initialization expression or in the definition of a tuple type, as the following example shows:

```

var t = (Sum: 4.5, Count: 3);
Console.WriteLine($"Sum of {t.Count} elements is {t.Sum}.");

(double Sum, int Count) d = (4.5, 3);
Console.WriteLine($"Sum of {d.Count} elements is {d.Sum}.");

```

Beginning with C# 7.1, if you don't specify a field name, it may be inferred from the name of the corresponding variable in a tuple initialization expression, as the following example shows:

```
var sum = 4.5;
var count = 3;
var t = (sum, count);
Console.WriteLine($"Sum of {t.count} elements is {t.sum}.");
```

That's known as tuple projection initializers. The name of a variable isn't projected onto a tuple field name in the following cases:

- The candidate name is a member name of a tuple type, for example, `Item3`, `ToString`, or `Rest`.
- The candidate name is a duplicate of another tuple field name, either explicit or implicit.

In those cases you either explicitly specify the name of a field or access a field by its default name.

The default names of tuple fields are `Item1`, `Item2`, `Item3` and so on. You can always use the default name of a field, even when a field name is specified explicitly or inferred, as the following example shows:

```
var a = 1;
var t = (a, b: 2, 3);
Console.WriteLine($"The 1st element is {t.Item1} (same as {t.a}).");
Console.WriteLine($"The 2nd element is {t.Item2} (same as {t.b}).");
Console.WriteLine($"The 3rd element is {t.Item3}.");
// Output:
// The 1st element is 1 (same as 1).
// The 2nd element is 2 (same as 2).
// The 3rd element is 3.
```

[Tuple assignment](#) and [tuple equality comparisons](#) don't take field names into account.

At compile time, the compiler replaces non-default field names with the corresponding default names. As a result, explicitly specified or inferred field names aren't available at run time.

Tuple assignment and deconstruction

C# supports assignment between tuple types that satisfy both of the following conditions:

- both tuple types have the same number of elements
- for each tuple position, the type of the right-hand tuple element is the same as or implicitly convertible to the type of the corresponding left-hand tuple element

Tuple element values are assigned following the order of tuple elements. The names of tuple fields are ignored and not assigned, as the following example shows:

```
(int, double) t1 = (17, 3.14);
(double First, double Second) t2 = (0.0, 1.0);
t2 = t1;
Console.WriteLine($"{nameof(t2)}: {t2.First} and {t2.Second}");
// Output:
// t2: 17 and 3.14

(double A, double B) t3 = (2.0, 3.0);
t3 = t2;
Console.WriteLine($"{nameof(t3)}: {t3.A} and {t3.B}");
// Output:
// t3: 17 and 3.14
```

You can also use the assignment operator `=` to *deconstruct* a tuple instance in separate variables. You can do that in one of the following ways:

- Explicitly declare the type of each variable inside parentheses:

```
var t = ("post office", 3.6);
(string destination, double distance) = t;
Console.WriteLine($"Distance to {destination} is {distance} kilometers.");
// Output:
// Distance to post office is 3.6 kilometers.
```

- Use the `var` keyword outside the parentheses to declare implicitly typed variables and let the compiler infer their types:

```
var t = ("post office", 3.6);
var (destination, distance) = t;
Console.WriteLine($"Distance to {destination} is {distance} kilometers.");
// Output:
// Distance to post office is 3.6 kilometers.
```

- Use existing variables:

```
var destination = string.Empty;
var distance = 0.0;

var t = ("post office", 3.6);
(destination, distance) = t;
Console.WriteLine($"Distance to {destination} is {distance} kilometers.");
// Output:
// Distance to post office is 3.6 kilometers.
```

For more information about deconstruction of tuples and other types, see [Deconstructing tuples and other types](#).

Tuple equality

Beginning with C# 7.3, tuple types support the `==` and `!=` operators. These operators compare members of the left-hand operand with the corresponding members of the right-hand operand following the order of tuple elements.

```
(int a, byte b) left = (5, 10);
(long a, int b) right = (5, 10);
Console.WriteLine(left == right); // output: True
Console.WriteLine(left != right); // output: False

var t1 = (A: 5, B: 10);
var t2 = (B: 5, A: 10);
Console.WriteLine(t1 == t2); // output: True
Console.WriteLine(t1 != t2); // output: False
```

As the preceding example shows, the `==` and `!=` operations don't take into account tuple field names.

Two tuples are comparable when both of the following conditions are satisfied:

- Both tuples have the same number of elements. For example, `t1 != t2` doesn't compile if `t1` and `t2` have different numbers of elements.
- For each tuple position, the corresponding elements from the left-hand and right-hand tuple operands are comparable with the `==` and `!=` operators. For example, `(1, (2, 3)) == ((1, 2), 3)` doesn't compile because `1` is not comparable with `(1, 2)`.

The `==` and `!=` operators compare tuples in short-circuiting way. That is, an operation stops as soon as it meets a pair of non equal elements or reaches the ends of tuples. However, before any comparison, *all* tuple elements are evaluated, as the following example shows:

```
Console.WriteLine((Display(1), Display(2)) == (Display(3), Display(4)));

int Display(int s)
{
    Console.WriteLine(s);
    return s;
}

// Output:
// 1
// 2
// 3
// 4
// False
```

Tuples as out parameters

Typically, you refactor a method that has `out` parameters into a method that returns a tuple. However, there are cases in which an `out` parameter can be of a tuple type. The following example shows how to work with tuples as `out` parameters:

```
var limitsLookup = new Dictionary<int, (int Min, int Max)>()
{
    [2] = (4, 10),
    [4] = (10, 20),
    [6] = (0, 23)
};

if (limitsLookup.TryGetValue(4, out (int Min, int Max) limits))
{
    Console.WriteLine($"Found limits: min is {limits.Min}, max is {limits.Max}");
}

// Output:
// Found limits: min is 10, max is 20
```

Tuples vs `System.Tuple`

C# tuples, which are backed by `System.ValueTuple` types, are different from tuples that are represented by `System.Tuple` types. The main differences are as follows:

- `System.ValueTuple` types are [value types](#). `System.Tuple` types are [reference types](#).
- `System.ValueTuple` types are mutable. `System.Tuple` types are immutable.
- Data members of `System.ValueTuple` types are fields. Data members of `System.Tuple` types are properties.

C# language specification

For more information, see the following feature proposal notes:

- [Infer tuple names \(aka. tuple projection initializers\)](#)
- [Support for `==` and `!=` on tuple types](#)

- `System.ValueTuple`

Nullable value types (C# reference)

12/28/2021 • 7 minutes to read • [Edit Online](#)

A *nullable value type* `T?` represents all values of its underlying *value type* `T` and an additional *null* value. For example, you can assign any of the following three values to a `bool?` variable: `true`, `false`, or `null`. An underlying value type `T` cannot be a nullable value type itself.

NOTE

C# 8.0 introduces the nullable reference types feature. For more information, see [Nullable reference types](#). The nullable value types are available beginning with C# 2.

Any nullable value type is an instance of the generic `System.Nullable<T>` structure. You can refer to a nullable value type with an underlying type `T` in any of the following interchangeable forms: `Nullable<T>` or `T?`.

You typically use a nullable value type when you need to represent the undefined value of an underlying value type. For example, a Boolean, or `bool`, variable can only be either `true` or `false`. However, in some applications a variable value can be undefined or missing. For example, a database field may contain `true` or `false`, or it may contain no value at all, that is, `NULL`. You can use the `bool?` type in that scenario.

Declaration and assignment

As a value type is implicitly convertible to the corresponding nullable value type, you can assign a value to a variable of a nullable value type as you would do that for its underlying value type. You can also assign the `null` value. For example:

```
double? pi = 3.14;
char? letter = 'a';

int m2 = 10;
int? m = m2;

bool? flag = null;

// An array of a nullable value type:
int?[] arr = new int?[10];
```

The default value of a nullable value type represents `null`, that is, it's an instance whose `Nullable<T>.HasValue` property returns `false`.

Examination of an instance of a nullable value type

Beginning with C# 7.0, you can use the `is` [operator with a type pattern](#) to both examine an instance of a nullable value type for `null` and retrieve a value of an underlying type:

```
int? a = 42;
if (a is int valueOfA)
{
    Console.WriteLine($"a is {valueOfA}");
}
else
{
    Console.WriteLine("a does not have a value");
}
// Output:
// a is 42
```

You always can use the following read-only properties to examine and get a value of a nullable value type variable:

- [Nullable<T>.HasValue](#) indicates whether an instance of a nullable value type has a value of its underlying type.
- [Nullable<T>.Value](#) gets the value of an underlying type if [HasValue](#) is `true`. If [HasValue](#) is `false`, the [Value](#) property throws an [InvalidOperationException](#).

The following example uses the `HasValue` property to test whether the variable contains a value before displaying it:

```
int? b = 10;
if (b.HasValue)
{
    Console.WriteLine($"b is {b.Value}");
}
else
{
    Console.WriteLine("b does not have a value");
}
// Output:
// b is 10
```

You can also compare a variable of a nullable value type with `null` instead of using the `HasValue` property, as the following example shows:

```
int? c = 7;
if (c != null)
{
    Console.WriteLine($"c is {c.Value}");
}
else
{
    Console.WriteLine("c does not have a value");
}
// Output:
// c is 7
```

Conversion from a nullable value type to an underlying type

If you want to assign a value of a nullable value type to a non-nullable value type variable, you might need to specify the value to be assigned in place of `null`. Use the [null-coalescing operator](#) `??` to do that (you can also use the [Nullable<T>.GetValueOrDefault\(T\)](#) method for the same purpose):

```
int? a = 28;
int b = a ?? -1;
Console.WriteLine($"b is {b}"); // output: b is 28

int? c = null;
int d = c ?? -1;
Console.WriteLine($"d is {d}"); // output: d is -1
```

If you want to use the [default](#) value of the underlying value type in place of `null`, use the [Nullable<T>.GetValueOrDefault\(\)](#) method.

You can also explicitly cast a nullable value type to a non-nullable type, as the following example shows:

```
int? n = null;

//int m1 = n;    // Doesn't compile
int n2 = (int)n; // Compiles, but throws an exception if n is null
```

At run time, if the value of a nullable value type is `null`, the explicit cast throws an [InvalidOperationException](#).

A non-nullable value type `T` is implicitly convertible to the corresponding nullable value type `T?`.

Lifted operators

The predefined unary and binary [operators](#) or any overloaded operators that are supported by a value type `T` are also supported by the corresponding nullable value type `T?`. These operators, also known as *lifted operators*, produce `null` if one or both operands are `null`; otherwise, the operator uses the contained values of its operands to calculate the result. For example:

```
int? a = 10;
int? b = null;
int? c = 10;

a++;           // a is 11
a = a * c;     // a is 110
a = a + b;     // a is null
```

NOTE

For the `bool?` type, the predefined `&` and `|` operators don't follow the rules described in this section: the result of an operator evaluation can be non-null even if one of the operands is `null`. For more information, see the [Nullable Boolean logical operators](#) section of the [Boolean logical operators](#) article.

For the [comparison operators](#) `<`, `>`, `<=`, and `>=`, if one or both operands are `null`, the result is `false`; otherwise, the contained values of operands are compared. Do not assume that because a particular comparison (for example, `<=`) returns `false`, the opposite comparison (`>`) returns `true`. The following example shows that 10 is

- neither greater than or equal to `null`
- nor less than `null`

```

int? a = 10;
Console.WriteLine($"{a} >= null is {a >= null}");
Console.WriteLine($"{a} < null is {a < null}");
Console.WriteLine($"{a} == null is {a == null}");
// Output:
// 10 >= null is False
// 10 < null is False
// 10 == null is False

int? b = null;
int? c = null;
Console.WriteLine($"null >= null is {b >= c}");
Console.WriteLine($"null == null is {b == c}");
// Output:
// null >= null is False
// null == null is True

```

For the [equality operator](#) `==`, if both operands are `null`, the result is `true`, if only one of the operands is `null`, the result is `false`; otherwise, the contained values of operands are compared.

For the [inequality operator](#) `!=`, if both operands are `null`, the result is `false`, if only one of the operands is `null`, the result is `true`; otherwise, the contained values of operands are compared.

If there exists a [user-defined conversion](#) between two value types, the same conversion can also be used between the corresponding nullable value types.

Boxing and unboxing

An instance of a nullable value type `T?` is [boxed](#) as follows:

- If [HasValue](#) returns `false`, the null reference is produced.
- If [HasValue](#) returns `true`, the corresponding value of the underlying value type `T` is boxed, not the instance of [Nullable<T>](#).

You can unbox a boxed value of a value type `T` to the corresponding nullable value type `T?`, as the following example shows:

```

int a = 41;
object aBoxed = a;
int? aNullable = (int?)aBoxed;
Console.WriteLine($"Value of aNullable: {aNullable}");

object aNullableBoxed = aNullable;
if (aNullableBoxed is int valueOfA)
{
    Console.WriteLine($"aNullableBoxed is boxed int: {valueOfA}");
}
// Output:
// Value of aNullable: 41
// aNullableBoxed is boxed int: 41

```

How to identify a nullable value type

The following example shows how to determine whether a [System.Type](#) instance represents a constructed nullable value type, that is, the [System.Nullable<T>](#) type with a specified type parameter `T`:

```

Console.WriteLine($"int? is {(Nullable.GetTypeOf(int?)) ? "nullable" : "non nullable"} value type");
Console.WriteLine($"int is {(Nullable.GetTypeOf(int)) ? "nullable" : "non-nullable"} value type");

bool IsNullable(Type type) => Nullable.GetUnderlyingType(type) != null;

// Output:
// int? is nullable value type
// int is non-nullable value type

```

As the example shows, you use the `typeof` operator to create a `System.Type` instance.

If you want to determine whether an instance is of a nullable value type, don't use the `Object.GetType` method to get a `Type` instance to be tested with the preceding code. When you call the `Object.GetType` method on an instance of a nullable value type, the instance is boxed to `Object`. As boxing of a non-null instance of a nullable value type is equivalent to boxing of a value of the underlying type, `GetType` returns a `Type` instance that represents the underlying type of a nullable value type:

```

int? a = 17;
Type typeOfA = a.GetType();
Console.WriteLine(typeOfA.FullName);
// Output:
// System.Int32

```

Also, don't use the `is` operator to determine whether an instance is of a nullable value type. As the following example shows, you cannot distinguish types of a nullable value type instance and its underlying type instance with the `is` operator:

```

int? a = 14;
if (a is int)
{
    Console.WriteLine("int? instance is compatible with int");
}

int b = 17;
if (b is int?)
{
    Console.WriteLine("int instance is compatible with int?");
}
// Output:
// int? instance is compatible with int
// int instance is compatible with int?

```

You can use the code presented in the following example to determine whether an instance is of a nullable value type:

```

int? a = 14;
Console.WriteLine(IsOfNullableType(a)); // output: True

int b = 17;
Console.WriteLine(IsOfNullableType(b)); // output: False

bool IsOfNullableType<T>(T o)
{
    var type = typeof(T);
    return Nullable.GetUnderlyingType(type) != null;
}

```

NOTE

The methods described in this section are not applicable in the case of [nullable reference types](#).

Reference types (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

There are two kinds of types in C#: reference types and value types. Variables of reference types store references to their data (objects), while variables of value types directly contain their data. With reference types, two variables can reference the same object; therefore, operations on one variable can affect the object referenced by the other variable. With value types, each variable has its own copy of the data, and it is not possible for operations on one variable to affect the other (except in the case of `in`, `ref` and `out` parameter variables; see [in](#), [ref](#) and [out](#) parameter modifier).

The following keywords are used to declare reference types:

- [class](#)
- [interface](#)
- [delegate](#)
- [record](#)

C# also provides the following built-in reference types:

- [dynamic](#)
- [object](#)
- [string](#)

See also

- [C# Reference](#)
- [C# Keywords](#)
- [Pointer types](#)
- [Value types](#)

Built-in reference types (C# reference)

12/28/2021 • 7 minutes to read • [Edit Online](#)

C# has a number of built-in reference types. They have keywords or operators that are synonyms for a type in the .NET library.

The object type

The `object` type is an alias for `System.Object` in .NET. In the unified type system of C#, all types, predefined and user-defined, reference types and value types, inherit directly or indirectly from `System.Object`. You can assign values of any type to variables of type `object`. Any `object` variable can be assigned to its default value using the literal `null`. When a variable of a value type is converted to object, it is said to be *boxed*. When a variable of type `object` is converted to a value type, it is said to be *unboxed*. For more information, see [Boxing and Unboxing](#).

The string type

The `string` type represents a sequence of zero or more Unicode characters. `string` is an alias for `System.String` in .NET.

Although `string` is a reference type, the [equality operators](#) `==` and `!=` are defined to compare the values of `string` objects, not references. This makes testing for string equality more intuitive. For example:

```
string a = "hello";
string b = "h";
// Append to contents of 'b'
b += "ello";
Console.WriteLine(a == b);
Console.WriteLine(object.ReferenceEquals(a, b));
```

This displays "True" and then "False" because the content of the strings are equivalent, but `a` and `b` do not refer to the same string instance.

The [+ operator](#) concatenates strings:

```
string a = "good " + "morning";
```

This creates a string object that contains "good morning".

Strings are *immutable*--the contents of a string object cannot be changed after the object is created, although the syntax makes it appear as if you can do this. For example, when you write this code, the compiler actually creates a new string object to hold the new sequence of characters, and that new object is assigned to `b`. The memory that had been allocated for `b` (when it contained the string "h") is then eligible for garbage collection.

```
string b = "h";
b += "ello";
```

The `[]` [operator](#) can be used for readonly access to individual characters of a string. Valid index values start at `0` and must be less than the length of the string:

```
string str = "test";
char x = str[2]; // x = 's';
```

In similar fashion, the `[]` operator can also be used for iterating over each character in a string:

```
string str = "test";

for (int i = 0; i < str.Length; i++)
{
    Console.Write(str[i] + " ");
}
// Output: t e s t
```

String literals are of type `string` and can be written in two forms, quoted and `@`-quoted. Quoted string literals are enclosed in double quotation marks (`"`):

```
"good morning" // a string literal
```

String literals can contain any character literal. Escape sequences are included. The following example uses escape sequence `\\` for backslash, `\u0066` for the letter `f`, and `\n` for newline.

```
string a = "\\u0066\n F";
Console.WriteLine(a);
// Output:
// \f
// F
```

NOTE

The escape code `\dddd` (where `dddd` is a four-digit number) represents the Unicode character U+`dddd`. Eight-digit Unicode escape codes are also recognized: `\Udddddddd`.

Verbatim string literals start with `@` and are also enclosed in double quotation marks. For example:

```
@"good morning" // a string literal
```

The advantage of verbatim strings is that escape sequences are *not* processed, which makes it easy to write, for example, a fully qualified Windows file name:

```
@"c:\Docs\Source\a.txt" // rather than "c:\\Docs\\Source\\a.txt"
```

To include a double quotation mark in an `@`-quoted string, double it:

```
@"""Ahoy!""" cried the captain." // "Ahoy!" cried the captain.
```

The delegate type

The declaration of a delegate type is similar to a method signature. It has a return value and any number of parameters of any type:

```
public delegate void MessageDelegate(string message);
public delegate int AnotherDelegate(MyType m, long num);
```

In .NET, `System.Action` and `System.Func` types provide generic definitions for many common delegates. You likely don't need to define new custom delegate types. Instead, you can create instantiations of the provided generic types.

A `delegate` is a reference type that can be used to encapsulate a named or an anonymous method. Delegates are similar to function pointers in C++; however, delegates are type-safe and secure. For applications of delegates, see [Delegates](#) and [Generic Delegates](#). Delegates are the basis for [Events](#). A delegate can be instantiated by associating it either with a named or anonymous method.

The delegate must be instantiated with a method or lambda expression that has a compatible return type and input parameters. For more information on the degree of variance that is allowed in the method signature, see [Variance in Delegates](#). For use with anonymous methods, the delegate and the code to be associated with it are declared together.

Delegate combination and removal fails with a runtime exception when the delegate types involved at run time are different due to variant conversion. The following example demonstrates a situation which fails:

```
Action<string> stringAction = str => {};
Action<object> objectAction = obj => {};

// Valid due to implicit reference conversion of
// objectAction to Action<string>, but may fail
// at run time.
Action<string> combination = stringAction + objectAction;
```

You can create a delegate with the correct runtime type by creating a new delegate object. The following example demonstrates how this workaround may be applied to the preceding example.

```
Action<string> stringAction = str => {};
Action<object> objectAction = obj => {};

// Creates a new delegate instance with a runtime type of Action<string>.
Action<string> wrappedObjectAction = new Action<string>(objectAction);

// The two Action<string> delegate instances can now be combined.
Action<string> combination = stringAction + wrappedObjectAction;
```

Beginning with C# 9, you can declare [function pointers](#), which use similar syntax. A function pointer uses the `calli` instruction instead of instantiating a delegate type and calling the virtual `Invoke` method.

The dynamic type

The `dynamic` type indicates that use of the variable and references to its members bypass compile-time type checking. Instead, these operations are resolved at run time. The `dynamic` type simplifies access to COM APIs such as the Office Automation APIs, to dynamic APIs such as IronPython libraries, and to the HTML Document Object Model (DOM).

Type `dynamic` behaves like type `object` in most circumstances. In particular, any non-null expression can be converted to the `dynamic` type. The `dynamic` type differs from `object` in that operations that contain expressions of type `dynamic` are not resolved or type checked by the compiler. The compiler packages together information about the operation, and that information is later used to evaluate the operation at run time. As part of the process, variables of type `dynamic` are compiled into variables of type `object`. Therefore, type `dynamic`

exists only at compile time, not at run time.

The following example contrasts a variable of type `dynamic` to a variable of type `object`. To verify the type of each variable at compile time, place the mouse pointer over `dyn` or `obj` in the `WriteLine` statements. Copy the following code into an editor where IntelliSense is available. IntelliSense shows **dynamic** for `dyn` and **object** for `obj`.

```
class Program
{
    static void Main(string[] args)
    {
        dynamic dyn = 1;
        object obj = 1;

        // Rest the mouse pointer over dyn and obj to see their
        // types at compile time.
        System.Console.WriteLine(dyn.GetType());
        System.Console.WriteLine(obj.GetType());
    }
}
```

The `WriteLine` statements display the run-time types of `dyn` and `obj`. At that point, both have the same type, integer. The following output is produced:

```
System.Int32
System.Int32
```

To see the difference between `dyn` and `obj` at compile time, add the following two lines between the declarations and the `WriteLine` statements in the previous example.

```
dyn = dyn + 3;
obj = obj + 3;
```

A compiler error is reported for the attempted addition of an integer and an object in expression `obj + 3`. However, no error is reported for `dyn + 3`. The expression that contains `dyn` is not checked at compile time because the type of `dyn` is `dynamic`.

The following example uses `dynamic` in several declarations. The `Main` method also contrasts compile-time type checking with run-time type checking.

```

using System;

namespace DynamicExamples
{
    class Program
    {
        static void Main(string[] args)
        {
            ExampleClass ec = new ExampleClass();
            Console.WriteLine(ec.exampleMethod(10));
            Console.WriteLine(ec.exampleMethod("value"));

            // The following line causes a compiler error because exampleMethod
            // takes only one argument.
            //Console.WriteLine(ec.exampleMethod(10, 4));

            dynamic dynamic_ec = new ExampleClass();
            Console.WriteLine(dynamic_ec.exampleMethod(10));

            // Because dynamic_ec is dynamic, the following call to exampleMethod
            // with two arguments does not produce an error at compile time.
            // However, it does cause a run-time error.
            //Console.WriteLine(dynamic_ec.exampleMethod(10, 4));
        }
    }

    class ExampleClass
    {
        static dynamic field;
        dynamic prop { get; set; }

        public dynamic exampleMethod(dynamic d)
        {
            dynamic local = "Local variable";
            int two = 2;

            if (d is int)
            {
                return local;
            }
            else
            {
                return two;
            }
        }
    }
}

// Results:
// Local variable
// 2
// Local variable

```

Records (C# reference)

12/28/2021 • 17 minutes to read • [Edit Online](#)

Beginning with C# 9, you use the `record` keyword to define a [reference type](#) that provides built-in functionality for encapsulating data. You can create record types with immutable properties by using positional parameters or standard property syntax:

```
public record Person(string FirstName, string LastName);
```

```
public record Person
{
    public string FirstName { get; init; } = default!;
    public string LastName { get; init; } = default!;
};
```

You can also create record types with mutable properties and fields:

```
public record Person
{
    public string FirstName { get; set; } = default!;
    public string LastName { get; set; } = default!;
};
```

While records can be mutable, they're primarily intended for supporting immutable data models. The record type offers the following features:

- [Concise syntax for creating a reference type with immutable properties](#)
- Built-in behavior useful for a data-centric reference type:
 - [Value equality](#)
 - [Concise syntax for nondestructive mutation](#)
 - [Built-in formatting for display](#)
- [Support for inheritance hierarchies](#)

You can also use [structure types](#) to design data-centric types that provide value equality and little or no behavior. In C# 10 and later, you can define `record struct` types using either positional parameters, or standard property syntax:

```
public readonly record struct Point(double X, double Y, double Z);
```

```
public record struct Point
{
    public double X { get; init; }
    public double Y { get; init; }
    public double Z { get; init; }
}
```

Record structs can be mutable as well, both positional record structs and record structs with no positional parameters:

```
public record struct DataMeasurement(DateTime TakenAt, double Measurement);
```

```
public record struct Point
{
    public double X { get; set; }
    public double Y { get; set; }
    public double Z { get; set; }
}
```

The preceding examples show some distinctions between records that are reference types and records that are value types:

- A `record` or a `record class` declares a reference type. The `class` keyword is optional, but can add clarity for readers. A `record struct` declares a value type.
- Positional properties are *immutable* in a `record class` and a `readonly record struct`. They're *mutable* in a `record struct`.

The remainder of this article discusses both `record class` and `record struct` types. The differences are detailed in each section. You should decide between a `record class` and a `record struct` similar to deciding between a `class` and a `struct`. The term *record* is used to describe behavior that applies to all record types. Either `record struct` or `record class` is used to describe behavior that applies to only struct or class types, respectively.

Positional syntax for property definition

You can use positional parameters to declare properties of a record and to initialize the property values when you create an instance:

```
public record Person(string FirstName, string LastName);

public static void Main()
{
    Person person = new("Nancy", "Davolio");
    Console.WriteLine(person);
    // output: Person { FirstName = Nancy, LastName = Davolio }
}
```

When you use the positional syntax for property definition, the compiler creates:

- A public auto-implemented property for each positional parameter provided in the record declaration.
 - For `record` types and `readonly record struct` types: An *init-only* property.
 - For `record struct` types: A read-write property.
- A primary constructor whose parameters match the positional parameters on the record declaration.
- For record struct types, a parameterless constructor that sets each field to its default value.
- A `Deconstruct` method with an `out` parameter for each positional parameter provided in the record declaration. The method deconstructs properties defined by using positional syntax; it ignores properties that are defined by using standard property syntax.

You may want to add attributes to any of these elements the compiler creates from the record definition. You can add a *target* to any attribute you apply to the positional record's properties. The following example applies the [System.Text.Json.Serialization.JsonPropertyNameAttribute](#) to each property of the `Person` record. The `property:` target indicates that the attribute is applied to the compiler-generated property. Other values are `field:` to apply the attribute to the field, and `param:` to apply the attribute to the parameter.

```

/// <summary>
/// Person record type
/// </summary>
/// <param name="FirstName">First Name</param>
/// <param name="LastName">Last Name</param>
/// <remarks>
/// The person type is a positional record containing the
/// properties for the first and last name. Those properties
/// map to the JSON elements "firstName" and "lastName" when
/// serialized or deserialized.
/// </remarks>
public record Person([property: JsonPropertyName("firstName")]string FirstName,
    [property: JsonPropertyName("lastName")]string LastName);

```

The preceding example also shows how to create XML documentation comments for the record. You can add the `<param>` tag to add documentation for the primary constructor's parameters.

If the generated auto-implemented property definition isn't what you want, you can define your own property of the same name. For example, you may want to change accessibility or mutability, or provide an implementation for either the `get` or `set` accessor. If you declare the property in your source, you must initialize it from the positional parameter of the record. The generated deconstructor will use your property definition. For instance, the following example declares the `FirstName` and `LastName` properties of a positional record `public`, but restricts the `Id` positional parameter to `internal`. You can use this syntax for records and record struct types.

```

public record Person(string FirstName, string LastName, string Id)
{
    internal string Id { get; init; } = Id;
}

public static void Main()
{
    Person person = new("Nancy", "Davolio", "12345");
    Console.WriteLine(person.FirstName); //output: Nancy
}

```

A record type doesn't have to declare any positional properties. You can declare a record without any positional properties, and you can declare other fields and properties, as in the following example:

```

public record Person(string FirstName, string LastName)
{
    public string[] PhoneNumbers { get; init; } = Array.Empty<string>();
};

```

If you define properties by using standard property syntax but omit the access modifier, the properties are implicitly `private`.

Immutability

A *positional record* and a *positional readonly record struct* declare init-only properties. A *positional record struct* declares read-write properties. You can override either of those defaults, as shown in the previous section.

Immutability can be useful when you need a data-centric type to be thread-safe or you're depending on a hash code remaining the same in a hash table. Immutability isn't appropriate for all data scenarios, however. [Entity Framework Core](#), for example, doesn't support updating with immutable entity types.

Init-only properties, whether created from positional parameters (`record class` , and `readonly record struct`) or by specifying `init` accessors, have *shallow immutability*. After initialization, you can't change the value of value-type properties or the reference of reference-type properties. However, the data that a reference-type property refers to can be changed. The following example shows that the content of a reference-type immutable property (an array in this case) is mutable:

```
public record Person(string FirstName, string LastName, string[] PhoneNumbers);

public static void Main()
{
    Person person = new("Nancy", "Davolio", new string[1] { "555-1234" });
    Console.WriteLine(person.PhoneNumbers[0]); // output: 555-1234

    person.PhoneNumbers[0] = "555-6789";
    Console.WriteLine(person.PhoneNumbers[0]); // output: 555-6789
}
```

The features unique to record types are implemented by compiler-synthesized methods, and none of these methods compromises immutability by modifying object state. Unless specified, the synthesized methods are generated for `record` , `record struct` , and `readonly record struct` declarations.

Value equality

For any type you define, you can override `Object.Equals(Object)`, and overload `operator ==` . If you don't override `Equals` or overload `operator ==` , the type you declare governs how equality is defined:

- For `class` types, two objects are equal if they refer to the same object in memory.
- For `struct` types, two objects are equal if they are of the same type and store the same values.
- For `record` types, including `record struct` and `readonly record struct` , two objects are equal if they are of the same type and store the same values.

The definition of equality for a `record struct` is the same as for a `struct` . The difference is that for a `struct` , the implementation is in `ValueType.Equals(Object)` and relies on reflection. For records, the implementation is compiler synthesized and uses the declared data members.

Reference equality is required for some data models. For example, [Entity Framework Core](#) depends on reference equality to ensure that it uses only one instance of an entity type for what is conceptually one entity. For this reason, records and record structs aren't appropriate for use as entity types in Entity Framework Core.

The following example illustrates value equality of record types:

```
public record Person(string FirstName, string LastName, string[] PhoneNumbers);

public static void Main()
{
    var phoneNumbers = new string[2];
    Person person1 = new("Nancy", "Davolio", phoneNumbers);
    Person person2 = new("Nancy", "Davolio", phoneNumbers);
    Console.WriteLine(person1 == person2); // output: True

    person1.PhoneNumbers[0] = "555-1234";
    Console.WriteLine(person1 == person2); // output: True

    Console.WriteLine(ReferenceEquals(person1, person2)); // output: False
}
```

To implement value equality, the compiler synthesizes the following methods:

- An override of `Object.Equals(Object)`.

This method is used as the basis for the `Object.Equals(Object, Object)` static method when both parameters are non-null.

- A virtual `Equals` method whose parameter is the record type. This method implements `IEquatable<T>`.
- An override of `Object.GetHashCode()`.
- Overrides of operators `==` and `!=`.

You can write your own implementations to replace any of these synthesized methods. If a record type has a method that matches the signature of any synthesized method, the compiler doesn't synthesize that method.

If you provide your own implementation of `Equals` in a record type, provide an implementation of `GetHashCode` also.

Nondestructive mutation

If you need to copy an instance with some modifications, you can use a `with` expression to achieve *nondestructive mutation*. A `with` expression makes a new record instance that is a copy of an existing record instance, with specified properties and fields modified. You use [object initializer](#) syntax to specify the values to be changed, as shown in the following example:

```
public record Person(string FirstName, string LastName)
{
    public string[] PhoneNumbers { get; init; }
}

public static void Main()
{
    Person person1 = new("Nancy", "Davolio") { PhoneNumbers = new string[1] };
    Console.WriteLine(person1);
    // output: Person { FirstName = Nancy, LastName = Davolio, PhoneNumbers = System.String[] }

    Person person2 = person1 with { FirstName = "John" };
    Console.WriteLine(person2);
    // output: Person { FirstName = John, LastName = Davolio, PhoneNumbers = System.String[] }
    Console.WriteLine(person1 == person2); // output: False

    person2 = person1 with { PhoneNumbers = new string[1] };
    Console.WriteLine(person2);
    // output: Person { FirstName = Nancy, LastName = Davolio, PhoneNumbers = System.String[] }
    Console.WriteLine(person1 == person2); // output: False

    person2 = person1 with { };
    Console.WriteLine(person1 == person2); // output: True
}
```

The `with` expression can set positional properties or properties created by using standard property syntax. Non-positional properties must have an `init` or `set` accessor to be changed in a `with` expression.

The result of a `with` expression is a *shallow copy*, which means that for a reference property, only the reference to an instance is copied. Both the original record and the copy end up with a reference to the same instance.

To implement this feature for `record class` types, the compiler synthesizes a clone method and a copy constructor. The virtual clone method returns a new record initialized by the copy constructor. When you use a `with` expression, the compiler creates code that calls the clone method and then sets the properties that are specified in the `with` expression.

If you need different copying behavior, you can write your own copy constructor in a `record class`. If you do

that, the compiler won't synthesize one. Make your constructor `private` if the record is `sealed`, otherwise make it `protected`. The compiler doesn't synthesize a copy constructor for `record struct` types. You can write one, but the compiler won't generate calls to it for `with` expressions. The values of the `record struct` are copied on assignment.

You can't override the clone method, and you can't create a member named `clone` in any record type. The actual name of the clone method is compiler-generated.

Built-in formatting for display

Record types have a compiler-generated `ToString` method that displays the names and values of public properties and fields. The `ToString` method returns a string of the following format:

```
<record type name> { <property name> = <value>, <property name> = <value>, ...}
```

The string printed for `<value>` is the string returned by the `ToString()` for the type of the property. In the following example, `ChildNames` is a `System.Array`, where `ToString` returns `System.String[]`:

```
Person { FirstName = Nancy, LastName = Davolio, ChildNames = System.String[] }
```

To implement this feature, in `record class` types, the compiler synthesizes a virtual `PrintMembers` method and a `ToString` override. In `record struct` types, this member is `private`. The `ToString` override creates a `StringBuilder` object with the type name followed by an opening bracket. It calls `PrintMembers` to add property names and values, then adds the closing bracket. The following example shows code similar to what the synthesized override contains:

```
public override string ToString()
{
    StringBuilder stringBuilder = new StringBuilder();
    stringBuilder.Append("Teacher"); // type name
    stringBuilder.Append(" { ");
    if (PrintMembers(stringBuilder))
    {
        stringBuilder.Append(" ");
    }
    stringBuilder.Append("}");
    return stringBuilder.ToString();
}
```

You can provide your own implementation of `PrintMembers` or the `ToString` override. Examples are provided in the [PrintMembers formatting in derived records](#) section later in this article. In C# 10 and later, your implementation of `ToString` may include the `sealed` modifier, which prevents the compiler from synthesizing a `ToString` implementation for any derived records. You can do this to create a consistent string representation throughout a hierarchy of `record` types. (Derived records will still have a `PrintMembers` method generated for all derived properties.)

Inheritance

This section only applies to `record class` types.

A record can inherit from another record. However, a record can't inherit from a class, and a class can't inherit from a record.

Positional parameters in derived record types

The derived record declares positional parameters for all the parameters in the base record primary constructor.

The base record declares and initializes those properties. The derived record doesn't hide them, but only creates and initializes properties for parameters that aren't declared in its base record.

The following example illustrates inheritance with positional property syntax:

```
public abstract record Person(string FirstName, string LastName);
public record Teacher(string FirstName, string LastName, int Grade)
    : Person(FirstName, LastName);
public static void Main()
{
    Person teacher = new Teacher("Nancy", "Davolio", 3);
    Console.WriteLine(teacher);
    // output: Teacher { FirstName = Nancy, LastName = Davolio, Grade = 3 }
}
```

Equality in inheritance hierarchies

This section applies to `record class` types, but not `record struct` types. For two record variables to be equal, the run-time type must be equal. The types of the containing variables might be different. Inherited equality comparison is illustrated in the following code example:

```
public abstract record Person(string FirstName, string LastName);
public record Teacher(string FirstName, string LastName, int Grade)
    : Person(FirstName, LastName);
public record Student(string FirstName, string LastName, int Grade)
    : Person(FirstName, LastName);
public static void Main()
{
    Person teacher = new Teacher("Nancy", "Davolio", 3);
    Person student = new Student("Nancy", "Davolio", 3);
    Console.WriteLine(teacher == student); // output: False

    Student student2 = new Student("Nancy", "Davolio", 3);
    Console.WriteLine(student2 == student); // output: True
}
```

In the example, all variables are declared as `Person`, even when the instance is a derived type of either `Student` or `Teacher`. The instances have the same properties and the same property values. But `student == teacher` returns `False` although both are `Person`-type variables, and `student == student2` returns `True` although one is a `Person` variable and one is a `Student` variable. The equality test depends on the runtime type of the actual object, not the declared type of the variable.

To implement this behavior, the compiler synthesizes an `EqualityContract` property that returns a `Type` object that matches the type of the record. The `EqualityContract` enables the equality methods to compare the runtime type of objects when they're checking for equality. If the base type of a record is `object`, this property is `virtual`. If the base type is another record type, this property is an override. If the record type is `sealed`, this property is effectively `sealed` because the type is `sealed`.

When comparing two instances of a derived type, the synthesized equality methods check all properties of the base and derived types for equality. The synthesized `GetHashCode` method uses the `GetHashCode` method from all properties and fields declared in the base type and the derived record type.

with expressions in derived records

The result of a `with` expression has the same run-time type as the expression's operand. All properties of the run-time type get copied, but you can only set properties of the compile-time type, as the following example shows:

```

public record Point(int X, int Y)
{
    public int Zbase { get; set; }
};
public record NamedPoint(string Name, int X, int Y) : Point(X, Y)
{
    public int Zderived { get; set; }
};

public static void Main()
{
    Point p1 = new NamedPoint("A", 1, 2) { Zbase = 3, Zderived = 4 };

    Point p2 = p1 with { X = 5, Y = 6, Zbase = 7 }; // Can't set Name or Zderived
    Console.WriteLine(p2 is NamedPoint); // output: True
    Console.WriteLine(p2);
    // output: NamedPoint { X = 5, Y = 6, Zbase = 7, Name = A, Zderived = 4 }

    Point p3 = (NamedPoint)p1 with { Name = "B", X = 5, Y = 6, Zbase = 7, Zderived = 8 };
    Console.WriteLine(p3);
    // output: NamedPoint { X = 5, Y = 6, Zbase = 7, Name = B, Zderived = 8 }
}

```

PrintMembers **formatting in derived records**

The synthesized `PrintMembers` method of a derived record type calls the base implementation. The result is that all public properties and fields of both derived and base types are included in the `ToString` output, as shown in the following example:

```

public abstract record Person(string FirstName, string LastName);
public record Teacher(string FirstName, string LastName, int Grade)
    : Person(FirstName, LastName);
public record Student(string FirstName, string LastName, int Grade)
    : Person(FirstName, LastName);

public static void Main()
{
    Person teacher = new Teacher("Nancy", "Davolio", 3);
    Console.WriteLine(teacher);
    // output: Teacher { FirstName = Nancy, LastName = Davolio, Grade = 3 }
}

```

You can provide your own implementation of the `PrintMembers` method. If you do that, use the following signature:

- For a `sealed` record that derives from `object` (doesn't declare a base record):
`private bool PrintMembers(StringBuilder builder);`
- For a `sealed` record that derives from another record (note that the enclosing type is `sealed`, so the method is effectively `sealed`): `protected override bool PrintMembers(StringBuilder builder);`
- For a record that isn't `sealed` and derives from `object`:
`protected virtual bool PrintMembers(StringBuilder builder);`
- For a record that isn't `sealed` and derives from another record:
`protected override bool PrintMembers(StringBuilder builder);`

Here's an example of code that replaces the synthesized `PrintMembers` methods, one for a record type that derives from `object`, and one for a record type that derives from another record:

```

public abstract record Person(string FirstName, string LastName, string[] PhoneNumbers)
{
    protected virtual bool PrintMembers(StringBuilder stringBuilder)
    {
        stringBuilder.Append($"FirstName = {FirstName}, LastName = {LastName}, ");
        stringBuilder.Append($"PhoneNumber1 = {PhoneNumbers[0]}, PhoneNumber2 = {PhoneNumbers[1]}");
        return true;
    }
}

public record Teacher(string FirstName, string LastName, string[] PhoneNumbers, int Grade)
    : Person(FirstName, LastName, PhoneNumbers)
{
    protected override bool PrintMembers(StringBuilder stringBuilder)
    {
        if (base.PrintMembers(stringBuilder))
        {
            stringBuilder.Append(", ");
        };
        stringBuilder.Append($"Grade = {Grade}");
        return true;
    }
};

public static void Main()
{
    Person teacher = new Teacher("Nancy", "Davolio", new string[2] { "555-1234", "555-6789" }, 3);
    Console.WriteLine(teacher);
    // output: Teacher { FirstName = Nancy, LastName = Davolio, PhoneNumber1 = 555-1234, PhoneNumber2 = 555-
    6789, Grade = 3 }
}

```

NOTE

In C# 10 and later, the compiler will synthesize `PrintMembers` in derived records even when a base record has sealed the `ToString` method. You can also create your own implementation of `PrintMembers`.

Deconstructor behavior in derived records

The `Deconstruct` method of a derived record returns the values of all positional properties of the compile-time type. If the variable type is a base record, only the base record properties are deconstructed unless the object is cast to the derived type. The following example demonstrates calling a deconstructor on a derived record.

```

public abstract record Person(string FirstName, string LastName);
public record Teacher(string FirstName, string LastName, int Grade)
    : Person(FirstName, LastName);
public record Student(string FirstName, string LastName, int Grade)
    : Person(FirstName, LastName);

public static void Main()
{
    Person teacher = new Teacher("Nancy", "Davolio", 3);
    var (firstName, lastName) = teacher; // Doesn't deconstruct Grade
    Console.WriteLine($"{firstName}, {lastName}");// output: Nancy, Davolio

    var (fName, lName, grade) = (Teacher)teacher;
    Console.WriteLine($"{fName}, {lName}, {grade}");// output: Nancy, Davolio, 3
}

```

Generic constraints

There's no generic constraint that requires a type to be a record. Records satisfy either the `class` or `struct` constraint. To make a constraint on a specific hierarchy of record types, put the constraint on the base record as you would a base class. For more information, see [Constraints on type parameters](#).

C# language specification

For more information, see the [Classes](#) section of the [C# language specification](#).

For more information about features introduced in C# 9 and later, see the following feature proposal notes:

- [Records](#)
- [Init-only setters](#)
- [Covariant returns](#)

- `with` expression

class (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Classes are declared using the keyword `class`, as shown in the following example:

```
class TestClass
{
    // Methods, properties, fields, events, delegates
    // and nested classes go here.
}
```

Remarks

Only single inheritance is allowed in C#. In other words, a class can inherit implementation from one base class only. However, a class can implement more than one interface. The following table shows examples of class inheritance and interface implementation:

INHERITANCE	EXAMPLE
None	<code>class ClassA { }</code>
Single	<code>class DerivedClass : BaseClass { }</code>
None, implements two interfaces	<code>class ImplClass : IFace1, IFace2 { }</code>
Single, implements one interface	<code>class ImplDerivedClass : BaseClass, IFace1 { }</code>

Classes that you declare directly within a namespace, not nested within other classes, can be either [public](#) or [internal](#). Classes are `internal` by default.

Class members, including nested classes, can be [public](#), [protected internal](#), [protected](#), [internal](#), [private](#), or [private protected](#). Members are `private` by default.

For more information, see [Access Modifiers](#).

You can declare generic classes that have type parameters. For more information, see [Generic Classes](#).

A class can contain declarations of the following members:

- [Constructors](#)
- [Constants](#)
- [Fields](#)
- [Finalizers](#)
- [Methods](#)
- [Properties](#)
- [Indexers](#)
- [Operators](#)

- [Events](#)
- [Delegates](#)
- [Classes](#)
- [Interfaces](#)
- [Structure types](#)
- [Enumeration types](#)

Example

The following example demonstrates declaring class fields, constructors, and methods. It also demonstrates object instantiation and printing instance data. In this example, two classes are declared. The first class, `Child`, contains two private fields (`name` and `age`), two public constructors and one public method. The second class, `StringTest`, is used to contain `Main`.

```

class Child
{
    private int age;
    private string name;

    // Default constructor:
    public Child()
    {
        name = "N/A";
    }

    // Constructor:
    public Child(string name, int age)
    {
        this.name = name;
        this.age = age;
    }

    // Printing method:
    public void PrintChild()
    {
        Console.WriteLine("{0}, {1} years old.", name, age);
    }
}

class StringTest
{
    static void Main()
    {
        // Create objects by using the new operator:
        Child child1 = new Child("Craig", 11);
        Child child2 = new Child("Sally", 10);

        // Create an object using the default constructor:
        Child child3 = new Child();

        // Display results:
        Console.Write("Child #1: ");
        child1.PrintChild();
        Console.Write("Child #2: ");
        child2.PrintChild();
        Console.Write("Child #3: ");
        child3.PrintChild();
    }
}
/* Output:
    Child #1: Craig, 11 years old.
    Child #2: Sally, 10 years old.
    Child #3: N/A, 0 years old.
*/

```

Comments

Notice that in the previous example the private fields (`name` and `age`) can only be accessed through the public method of the `Child` class. For example, you cannot print the child's name, from the `Main` method, using a statement like this:

```
Console.Write(child1.name);    // Error
```

Accessing private members of `Child` from `Main` would only be possible if `Main` were a member of the class.

Types declared inside a class without an access modifier default to `private`, so the data members in this

example would still be `private` if the keyword were removed.

Finally, notice that for the object created using the parameterless constructor (`child3`), the `age` field was initialized to zero by default.

C# language specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

interface (C# Reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

An interface defines a contract. Any `class` or `struct` that implements that contract must provide an implementation of the members defined in the interface. Beginning with C# 8.0, an interface may define a default implementation for members. It may also define `static` members in order to provide a single implementation for common functionality.

In the following example, class `ImplementationClass` must implement a method named `SampleMethod` that has no parameters and returns `void`.

For more information and examples, see [Interfaces](#).

Example interface

```
interface ISampleInterface
{
    void SampleMethod();
}

class ImplementationClass : ISampleInterface
{
    // Explicit interface member implementation:
    void ISampleInterface.SampleMethod()
    {
        // Method implementation.
    }

    static void Main()
    {
        // Declare an interface instance.
        ISampleInterface obj = new ImplementationClass();

        // Call the member.
        obj.SampleMethod();
    }
}
```

An interface can be a member of a namespace or a class. An interface declaration can contain declarations (signatures without any implementation) of the following members:

- [Methods](#)
- [Properties](#)
- [Indexers](#)
- [Events](#)

These preceding member declarations typically do not contain a body. Beginning with C# 8.0, an interface member may declare a body. This is called a *default implementation*. Members with bodies permit the interface to provide a "default" implementation for classes and structs that don't provide an overriding implementation. In addition, beginning with C# 8.0, an interface may include:

- [Constants](#)
- [Operators](#)
- [Static constructor](#).

- [Nested types](#)
- [Static fields, methods, properties, indexers, and events](#)
- Member declarations using the explicit interface implementation syntax.
- Explicit access modifiers (the default access is `public`).

Interfaces may not contain instance state. While static fields are now permitted, instance fields are not permitted in interfaces. [Instance auto-properties](#) are not supported in interfaces, as they would implicitly declare a hidden field. This rule has a subtle effect on property declarations. In an interface declaration, the following code does not declare an auto-implemented property as it does in a `class` or `struct`. Instead, it declares a property that doesn't have a default implementation but must be implemented in any type that implements the interface:

```
public interface INamed
{
    public string Name {get; set;}
}
```

An interface can inherit from one or more base interfaces. When an interface [overrides a method](#) implemented in a base interface, it must use the [explicit interface implementation](#) syntax.

When a base type list contains a base class and interfaces, the base class must come first in the list.

A class that implements an interface can explicitly implement members of that interface. An explicitly implemented member cannot be accessed through a class instance, but only through an instance of the interface. In addition, default interface members can only be accessed through an instance of the interface.

For more information about explicit interface implementation, see [Explicit Interface Implementation](#).

Example interface implementation

The following example demonstrates interface implementation. In this example, the interface contains the property declaration and the class contains the implementation. Any instance of a class that implements `IPoint` has integer properties `x` and `y`.

```

interface IPoint
{
    // Property signatures:
    int X
    {
        get;
        set;
    }

    int Y
    {
        get;
        set;
    }

    double Distance
    {
        get;
    }
}

class Point : IPoint
{
    // Constructor:
    public Point(int x, int y)
    {
        X = x;
        Y = y;
    }

    // Property implementation:
    public int X { get; set; }

    public int Y { get; set; }

    // Property implementation
    public double Distance =>
        Math.Sqrt(X * X + Y * Y);
}

class MainClass
{
    static void PrintPoint(IPoint p)
    {
        Console.WriteLine("x={0}, y={1}", p.X, p.Y);
    }

    static void Main()
    {
        IPoint p = new Point(2, 3);
        Console.Write("My Point: ");
        PrintPoint(p);
    }
}
// Output: My Point: x=2, y=3

```

C# language specification

Nullable reference types (C# reference)

12/28/2021 • 5 minutes to read • [Edit Online](#)

NOTE

This article covers nullable reference types. You can also declare [nullable value types](#).

Nullable reference types are available beginning with C# 8.0, in code that has opted in to a *nullable aware context*. Nullable reference types, the null static analysis warnings, and the [null-forgiving operator](#) are optional language features. All are turned off by default. A *nullable context* is controlled at the project level using build settings, or in code using pragmas.

In a nullable aware context:

- A variable of a reference type `T` must be initialized with non-null, and may never be assigned a value that may be `null`.
- A variable of a reference type `T?` may be initialized with `null` or assigned `null`, but is required to be checked against `null` before de-referencing.
- A variable `m` of type `T?` is considered to be non-null when you apply the null-forgiving operator, as in `m!`.

The distinctions between a non-nullable reference type `T` and a nullable reference type `T?` are enforced by the compiler's interpretation of the preceding rules. A variable of type `T` and a variable of type `T?` are represented by the same .NET type. The following example declares a non-nullable string and a nullable string, and then uses the null-forgiving operator to assign a value to a non-nullable string:

```
string notNull = "Hello";
string? nullable = default;
notNull = nullable!; // null forgiveness
```

The variables `notNull` and `nullable` are both represented by the [String](#) type. Because the non-nullable and nullable types are both stored as the same type, there are several locations where using a nullable reference type isn't allowed. In general, a nullable reference type can't be used as a base class or implemented interface. A nullable reference type can't be used in any object creation or type testing expression. A nullable reference type can't be the type of a member access expression. The following examples show these constructs:

```
public MyClass : System.Object? // not allowed
{
}

var nullEmpty = System.String?.Empty; // Not allowed
var maybeObject = new object?(); // Not allowed
try
{
    if (thing is string? nullableString) // not allowed
        Console.WriteLine(nullableString);
} catch (Exception? e) // Not Allowed
{
    Console.WriteLine("error");
}
```

Nullable references and static analysis

The examples in the previous section illustrate the nature of nullable reference types. Nullable reference types aren't new class types, but rather annotations on existing reference types. The compiler uses those annotations to help you find potential null reference errors in your code. There's no runtime difference between a non-nullable reference type and a nullable reference type. The compiler doesn't add any runtime checking for non-nullable reference types. The benefits are in the compile-time analysis. The compiler generates warnings that help you find and fix potential null errors in your code. You declare your intent, and the compiler warns you when your code violates that intent.

In a nullable enabled context, the compiler performs static analysis on variables of any reference type, both nullable and non-nullable. The compiler tracks the *null-state* of each reference variable as either *not-null* or *maybe-null*. The default state of a non-nullable reference is *not-null*. The default state of a nullable reference is *maybe-null*.

Non-nullable reference types should always be safe to dereference because their *null-state* is *not-null*. To enforce that rule, the compiler issues warnings if a non-nullable reference type isn't initialized to a non-null value. Local variables must be assigned where they're declared. Every field must be assigned a *not-null* value, in a field initializer or every constructor. The compiler issues warnings when a non-nullable reference is assigned to a reference whose state is *maybe-null*. Generally, a non-nullable reference is *not-null* and no warnings are issued when those variables are dereferenced.

NOTE

If you assign a *maybe-null* expression to a non-nullable reference type, the compiler generates a warnings. The compiler then generates warnings for that variable until it's assigned to a *not-null* expression.

Nullable reference types may be initialized or assigned to `null`. Therefore, static analysis must determine that a variable is *not-null* before it's dereferenced. If a nullable reference is determined to be *maybe-null*, assigning to a non-nullable reference variable generates a compiler warning. The following class shows examples of these warnings:

```

public class ProductDescription
{
    private string shortDescription;
    private string? detailedDescription;

    public ProductDescription() // Warning! shortDescription not initialized.
    {
    }

    public ProductDescription(string productDescription) =>
        this.shortDescription = productDescription;

    public void SetDescriptions(string productDescription, string? details=null)
    {
        shortDescription = productDescription;
        detailedDescription = details;
    }

    public string GetDescription()
    {
        if (detailedDescription.Length == 0) // Warning! dereference possible null
        {
            return shortDescription;
        }
        else
        {
            return $"{shortDescription}\n{detailedDescription}";
        }
    }

    public string FullDescription()
    {
        if (detailedDescription == null)
        {
            return shortDescription;
        }
        else if (detailedDescription.Length > 0) // OK, detailedDescription can't be null.
        {
            return $"{shortDescription}\n{detailedDescription}";
        }
        return shortDescription;
    }
}

```

The following snippet shows where the compiler emits warnings when using this class:

```

string shortDescription = default; // Warning! non-nullable set to null;
var product = new ProductDescription(shortDescription); // Warning! static analysis knows shortDescription
maybe null.

string description = "widget";
var item = new ProductDescription(description);

item.SetDescriptions(description, "These widgets will do everything.");

```

The preceding examples demonstrate how compiler's static analysis determines the *null-state* of reference variables. The compiler applies language rules for null checks and assignments to inform its analysis. The compiler can't make assumptions about the semantics of methods or properties. If you call methods that perform null checks, the compiler can't know those methods affect a variable's *null-state*. There are attributes you can add to your APIs to inform the compiler about the semantics of arguments and return values. These attributes have been applied to many common APIs in the .NET Core libraries. For example, [IsNullOrEmpty](#) has been updated, and the compiler correctly interprets that method as a null check. For more information about the

attributes that apply to *null-state* static analysis, see the article on [Nullable attributes](#).

Setting the nullable context

There are two ways to control the nullable context. At the project level, you can add the `<Nullable>enable</Nullable>` project setting. In a single C# source file, you can add the `#nullable enable` pragma to enable the nullable context. See the article on [setting a nullable strategy](#). Prior to .NET 6, new projects use the default, `<Nullable>disable</Nullable>`. Beginning with .NET 6, new projects include the `<Nullable>enable</Nullable>` element in the project file.

C# language specification

For more information, see the following proposals for the [C# language specification](#):

- [Nullable reference types](#)
- [Draft nullable reference types specification](#)

See also

- [C# reference](#)
- [Nullable value types](#)

void (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

You use `void` as the return type of a [method](#) (or a [local function](#)) to specify that the method doesn't return a value.

```
public static void Display(IEnumerable<int> numbers)
{
    if (numbers is null)
    {
        return;
    }

    Console.WriteLine(string.Join(" ", numbers));
}
```

You can also use `void` as a referent type to declare a pointer to an unknown type. For more information, see [Pointer types](#).

You cannot use `void` as the type of a variable.

See also

- [C# reference](#)
- [System.Void](#)

var (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Beginning with C# 3, variables that are declared at method scope can have an implicit "type" `var`. An implicitly typed local variable is strongly typed just as if you had declared the type yourself, but the compiler determines the type. The following two declarations of `i` are functionally equivalent:

```
var i = 10; // Implicitly typed.  
int i = 10; // Explicitly typed.
```

IMPORTANT

When `var` is used with [nullable reference types](#) enabled, it always implies a nullable reference type even if the expression type isn't nullable. The compiler's null state analysis protects against dereferencing a potential `null` value. If the variable is never assigned to an expression that maybe null, the compiler won't emit any warnings. If you assign the variable to an expression that might be null, you must test that it isn't null before dereferencing it to avoid any warnings.

A common use of the `var` keyword is with constructor invocation expressions. The use of `var` allows you to not repeat a type name in a variable declaration and object instantiation, as the following example shows:

```
var xs = new List<int>();
```

Beginning with C# 9.0, you can use a target-typed `new` expression as an alternative:

```
List<int> xs = new();  
List<int>? ys = new();
```

In pattern matching, the `var` keyword is used in a `var` pattern.

Example

The following example shows two query expressions. In the first expression, the use of `var` is permitted but is not required, because the type of the query result can be stated explicitly as an `IEnumerable<string>`. However, in the second expression, `var` allows the result to be a collection of anonymous types, and the name of that type is not accessible except to the compiler itself. Use of `var` eliminates the requirement to create a new class for the result. Note that in Example #2, the `foreach` iteration variable `item` must also be implicitly typed.

```

// Example #1: var is optional when
// the select clause specifies a string
string[] words = { "apple", "strawberry", "grape", "peach", "banana" };
var wordQuery = from word in words
                 where word[0] == 'g'
                 select word;

// Because each element in the sequence is a string,
// not an anonymous type, var is optional here also.
foreach (string s in wordQuery)
{
    Console.WriteLine(s);
}

// Example #2: var is required because
// the select clause specifies an anonymous type
var custQuery = from cust in customers
                 where cust.City == "Phoenix"
                 select new { cust.Name, cust.Phone };

// var must be used because each item
// in the sequence is an anonymous type
foreach (var item in custQuery)
{
    Console.WriteLine("Name={0}, Phone={1}", item.Name, item.Phone);
}

```

Built-in types (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The following table lists the C# built-in [value](#) types:

C# TYPE KEYWORD	.NET TYPE
<code>bool</code>	<code>System.Boolean</code>
<code>byte</code>	<code>System.Byte</code>
<code>sbyte</code>	<code>System.SByte</code>
<code>char</code>	<code>System.Char</code>
<code>decimal</code>	<code>System.Decimal</code>
<code>double</code>	<code>System.Double</code>
<code>float</code>	<code>System.Single</code>
<code>int</code>	<code>System.Int32</code>
<code>uint</code>	<code>System.UInt32</code>
<code>nint</code>	<code>System.IntPtr</code>
<code>nuint</code>	<code>System.UIntPtr</code>
<code>long</code>	<code>System.Int64</code>
<code>ulong</code>	<code>System.UInt64</code>
<code>short</code>	<code>System.Int16</code>
<code>ushort</code>	<code>System.UInt16</code>

The following table lists the C# built-in [reference](#) types:

C# TYPE KEYWORD	.NET TYPE
<code>object</code>	<code>System.Object</code>
<code>string</code>	<code>System.String</code>
<code>dynamic</code>	<code>System.Object</code>

In the preceding tables, each C# type keyword from the left column (except [nint](#) and [nuint](#) and [dynamic](#)) is an

alias for the corresponding .NET type. They are interchangeable. For example, the following declarations declare variables of the same type:

```
int a = 123;  
System.Int32 b = 123;
```

The `int` and `uint` types are native-sized integers. They are represented internally by the indicated .NET types, but in each case the keyword and the .NET type are not interchangeable. The compiler provides operations and conversions for `int` and `uint` as integer types that it doesn't provide for the pointer types `System.IntPtr` and `System.UIntPtr`. For more information, see [int and uint types](#).

The `void` keyword represents the absence of a type. You use it as the return type of a method that doesn't return a value.

Unmanaged types (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

A type is an **unmanaged type** if it's any of the following types:

- `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, or `bool`
- Any **enum** type
- Any **pointer** type
- Any user-defined **struct** type that contains fields of unmanaged types only and, in C# 7.3 and earlier, is not a constructed type (a type that includes at least one type argument)

Beginning with C# 7.3, you can use the **unmanaged** **constraint** to specify that a type parameter is a non-pointer, non-nullable unmanaged type.

Beginning with C# 8.0, a *constructed* struct type that contains fields of unmanaged types only is also unmanaged, as the following example shows:

```
using System;

public struct Coords<T>
{
    public T X;
    public T Y;
}

public class UnmanagedType
{
    public static void Main()
    {
        DisplaySize<Coords<int>>();
        DisplaySize<Coords<double>>();
    }

    private unsafe static void DisplaySize<T>() where T : unmanaged
    {
        Console.WriteLine($"{typeof(T)} is unmanaged and its size is {sizeof(T)} bytes");
    }
}

// Output:
// Coords`1[System.Int32] is unmanaged and its size is 8 bytes
// Coords`1[System.Double] is unmanaged and its size is 16 bytes
```

A generic struct may be the source of both unmanaged and not unmanaged constructed types. The preceding example defines a generic struct `Coords<T>` and presents the examples of unmanaged constructed types. The example of not an unmanaged type is `Coords<object>`. It's not unmanaged because it has the fields of the `object` type, which is not unmanaged. If you want *all* constructed types to be unmanaged types, use the **unmanaged** constraint in the definition of a generic struct:

```
public struct Coords<T> where T : unmanaged
{
    public T X;
    public T Y;
}
```

C# language specification

Default values of C# types (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The following table shows the default values of C# types:

TYPE	DEFAULT VALUE
Any reference type	<code>null</code>
Any built-in integral numeric type	0 (zero)
Any built-in floating-point numeric type	0 (zero)
bool	<code>false</code>
char	<code>'\0'</code> (U+0000)
enum	The value produced by the expression <code>(E)0</code> , where <code>E</code> is the enum identifier.
struct	The value produced by setting all value-type fields to their default values and all reference-type fields to <code>null</code> .
Any nullable value type	An instance for which the HasValue property is <code>false</code> and the Value property is undefined. That default value is also known as the <i>null</i> value of a nullable value type.

Default value expressions

Use the [default](#) operator to produce the default value of a type, as the following example shows:

```
int a = default(int);
```

Beginning with C# 7.1, you can use the [default](#) literal to initialize a variable with the default value of its type:

```
int a = default;
```

Parameterless constructor of a value type

For a value type, the *implicit* parameterless constructor also produces the default value of the type, as the following example shows:

```
var n = new System.Numerics.Complex();  
Console.WriteLine(n); // output: (0, 0)
```

At run time, if the [System.Type](#) instance represents a value type, you can use the [Activator.CreateInstance\(Type\)](#) method to invoke the parameterless constructor to obtain the default value of the type.

NOTE

In C# 10 and later, a [structure type](#) (which is a value type) may have an [explicit parameterless constructor](#) that may produce a non-default value of the type. Thus, we recommend using the `default` operator or the `default` literal to produce the default value of a type.

C# language specification

C# Keywords

12/28/2021 • 2 minutes to read • [Edit Online](#)

Keywords are predefined, reserved identifiers that have special meanings to the compiler. They cannot be used as identifiers in your program unless they include `@` as a prefix. For example, `@if` is a valid identifier, but `if` is not because `if` is a keyword.

The first table in this topic lists keywords that are reserved identifiers in any part of a C# program. The second table in this topic lists the contextual keywords in C#. Contextual keywords have special meaning only in a limited program context and can be used as identifiers outside that context. Generally, as new keywords are added to the C# language, they are added as contextual keywords in order to avoid breaking programs written in earlier versions.

Access Modifiers (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Access modifiers are keywords used to specify the declared accessibility of a member or a type. This section introduces the four access modifiers:

- `public`
- `protected`
- `internal`
- `private`

The following six accessibility levels can be specified using the access modifiers:

- `public` : Access is not restricted.
- `protected` : Access is limited to the containing class or types derived from the containing class.
- `internal` : Access is limited to the current assembly.
- `protected internal` : Access is limited to the current assembly or types derived from the containing class.
- `private` : Access is limited to the containing type.
- `private protected` : Access is limited to the containing class or types derived from the containing class within the current assembly.

This section also introduces the following:

- [Accessibility Levels](#): Using the four access modifiers to declare six levels of accessibility.
- [Accessibility Domain](#): Specifies where, in the program sections, a member can be referenced.
- [Restrictions on Using Accessibility Levels](#): A summary of the restrictions on using declared accessibility levels.

- [Modifiers](#)

Accessibility Levels (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Use the access modifiers, `public`, `protected`, `internal`, or `private`, to specify one of the following declared accessibility levels for members.

DECLARED ACCESSIBILITY	MEANING
<code>public</code>	Access is not restricted.
<code>protected</code>	Access is limited to the containing class or types derived from the containing class.
<code>internal</code>	Access is limited to the current assembly.
<code>protected internal</code>	Access is limited to the current assembly or types derived from the containing class.
<code>private</code>	Access is limited to the containing type.
<code>private protected</code>	Access is limited to the containing class or types derived from the containing class within the current assembly. Available since C# 7.2.

Only one access modifier is allowed for a member or type, except when you use the `protected internal` or `private protected` combinations.

Access modifiers are not allowed on namespaces. Namespaces have no access restrictions.

Depending on the context in which a member declaration occurs, only certain declared accessibilities are permitted. If no access modifier is specified in a member declaration, a default accessibility is used.

Top-level types, which are not nested in other types, can only have `internal` or `public` accessibility. The default accessibility for these types is `internal`.

Nested types, which are members of other types, can have declared accessibilities as indicated in the following table.

MEMBERS OF	DEFAULT MEMBER ACCESSIBILITY	ALLOWED DECLARED ACCESSIBILITY OF THE MEMBER
<code>enum</code>	<code>public</code>	None

MEMBERS OF	DEFAULT MEMBER ACCESSIBILITY	ALLOWED DECLARED ACCESSIBILITY OF THE MEMBER
<code>class</code>	<code>private</code>	<code>public</code> <code>protected</code> <code>internal</code> <code>private</code> <code>protected internal</code> <code>private protected</code>
<code>interface</code>	<code>public</code>	<code>public</code> <code>protected</code> <code>internal</code> <code>private</code> * <code>protected internal</code> <code>private protected</code>
<code>struct</code>	<code>private</code>	<code>public</code> <code>internal</code> <code>private</code>

* An `interface` member with `private` accessibility must have a default implementation.

The accessibility of a nested type depends on its [accessibility domain](#), which is determined by both the declared accessibility of the member and the accessibility domain of the immediately containing type. However, the accessibility domain of a nested type cannot exceed that of the containing type.

C# Language Specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

Accessibility Domain (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The accessibility domain of a member specifies in which program sections a member can be referenced. If the member is nested within another type, its accessibility domain is determined by both the [accessibility level](#) of the member and the accessibility domain of the immediately containing type.

The accessibility domain of a top-level type is at least the program text of the project that it is declared in. That is, the domain includes all of the source files of this project. The accessibility domain of a nested type is at least the program text of the type in which it is declared. That is, the domain is the type body, which includes all nested types. The accessibility domain of a nested type never exceeds that of the containing type. These concepts are demonstrated in the following example.

Example

This example contains a top-level type, `T1`, and two nested classes, `M1` and `M2`. The classes contain fields that have different declared accessibilities. In the `Main` method, a comment follows each statement to indicate the accessibility domain of each member. Notice that the statements that try to reference the inaccessible members are commented out. If you want to see the compiler errors caused by referencing an inaccessible member, remove the comments one at a time.

```
public class T1
{
    public static int publicInt;
    internal static int internalInt;
    private static int privateInt = 0;

    static T1()
    {
        // T1 can access public or internal members
        // in a public or private (or internal) nested class.
        M1.publicInt = 1;
        M1.internalInt = 2;
        M2.publicInt = 3;
        M2.internalInt = 4;

        // Cannot access the private member privateInt
        // in either class:
        // M1.privateInt = 2; //CS0122
    }

    public class M1
    {
        public static int publicInt;
        internal static int internalInt;
        private static int privateInt = 0;
    }

    private class M2
    {
        public static int publicInt = 0;
        internal static int internalInt = 0;
        private static int privateInt = 0;
    }
}

class MainClass
{
```

```

static void Main()
{
    // Access is unlimited.
    T1.publicInt = 1;

    // Accessible only in current assembly.
    T1.internalInt = 2;

    // Error CS0122: inaccessible outside T1.
    // T1.privateInt = 3;

    // Access is unlimited.
    T1.M1.publicInt = 1;

    // Accessible only in current assembly.
    T1.M1.internalInt = 2;

    // Error CS0122: inaccessible outside M1.
    //     T1.M1.privateInt = 3;

    // Error CS0122: inaccessible outside T1.
    //     T1.M2.publicInt = 1;

    // Error CS0122: inaccessible outside T1.
    //     T1.M2.internalInt = 2;

    // Error CS0122: inaccessible outside M2.
    //     T1.M2.privateInt = 3;

    // Keep the console open in debug mode.
    System.Console.WriteLine("Press any key to exit.");
    System.Console.ReadKey();
}
}

```

Restrictions on using accessibility levels (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

When you specify a type in a declaration, check whether the accessibility level of the type is dependent on the accessibility level of a member or of another type. For example, the direct base class must be at least as accessible as the derived class. The following declarations cause a compiler error because the base class

`BaseClass` is less accessible than `MyClass`:

```
class BaseClass {...}  
public class MyClass: BaseClass {...} // Error
```

The following table summarizes the restrictions on declared accessibility levels.

CONTEXT	REMARKS
Classes	The direct base class of a class type must be at least as accessible as the class type itself.
Interfaces	The explicit base interfaces of an interface type must be at least as accessible as the interface type itself.
Delegates	The return type and parameter types of a delegate type must be at least as accessible as the delegate type itself.
Constants	The type of a constant must be at least as accessible as the constant itself.
Fields	The type of a field must be at least as accessible as the field itself.
Methods	The return type and parameter types of a method must be at least as accessible as the method itself.
Properties	The type of a property must be at least as accessible as the property itself.
Events	The type of an event must be at least as accessible as the event itself.
Indexers	The type and parameter types of an indexer must be at least as accessible as the indexer itself.
Operators	The return type and parameter types of an operator must be at least as accessible as the operator itself.
Constructors	The parameter types of a constructor must be at least as accessible as the constructor itself.

Example

The following example contains erroneous declarations of different types. The comment following each declaration indicates the expected compiler error.

```
// Restrictions on Using Accessibility Levels
// CS0052 expected as well as CS0053, CS0056, and CS0057
// To make the program work, change access level of both class B
// and MyPrivateMethod() to public.

using System;

// A delegate:
delegate int MyDelegate();

class B
{
    // A private method:
    static int MyPrivateMethod()
    {
        return 0;
    }
}

public class A
{
    // Error: The type B is less accessible than the field A.myField.
    public B myField = new B();

    // Error: The type B is less accessible
    // than the constant A.myConst.
    public readonly B myConst = new B();

    public B MyMethod()
    {
        // Error: The type B is less accessible
        // than the method A.MyMethod.
        return new B();
    }

    // Error: The type B is less accessible than the property A.MyProp
    public B MyProp
    {
        set
        {
        }
    }

    MyDelegate d = new MyDelegate(B.MyPrivateMethod);
    // Even when B is declared public, you still get the error:
    // "The parameter B.MyPrivateMethod is not accessible due to
    // protection level."

    public static B operator +(A m1, B m2)
    {
        // Error: The type B is less accessible
        // than the operator A.operator +(A,B)
        return new B();
    }

    static void Main()
    {
        Console.Write("Compiled successfully");
    }
}
```

- [internal](#)

internal (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `internal` keyword is an [access modifier](#) for types and type members.

This page covers `internal` access. The `internal` keyword is also part of the `protected internal` access modifier.

Internal types or members are accessible only within files in the same assembly, as in this example:

```
public class BaseClass
{
    // Only accessible within the same assembly.
    internal static int x = 0;
}
```

For a comparison of `internal` with the other access modifiers, see [Accessibility Levels](#) and [Access Modifiers](#).

For more information about assemblies, see [Assemblies in .NET](#).

A common use of internal access is in component-based development because it enables a group of components to cooperate in a private manner without being exposed to the rest of the application code. For example, a framework for building graphical user interfaces could provide `Control` and `Form` classes that cooperate by using members with internal access. Since these members are internal, they are not exposed to code that is using the framework.

It is an error to reference a type or a member with internal access outside the assembly within which it was defined.

Example 1

This example contains two files, `Assembly1.cs` and `Assembly1_a.cs`. The first file contains an internal base class, `BaseClass`. In the second file, an attempt to instantiate `BaseClass` will produce an error.

```
// Assembly1.cs
// Compile with: /target:library
internal class BaseClass
{
    public static int intM = 0;
}
```

```
// Assembly1_a.cs
// Compile with: /reference:Assembly1.dll
class TestAccess
{
    static void Main()
    {
        var myBase = new BaseClass(); // CS0122
    }
}
```

Example 2

In this example, use the same files you used in example 1, and change the accessibility level of `BaseClass` to `public`. Also change the accessibility level of the member `intM` to `internal`. In this case, you can instantiate the class, but you cannot access the internal member.

```
// Assembly2.cs
// Compile with: /target:library
public class BaseClass
{
    internal static int intM = 0;
}
```

```
// Assembly2_a.cs
// Compile with: /reference:Assembly2.dll
public class TestAccess
{
    static void Main()
    {
        var myBase = new BaseClass();    // Ok.
        BaseClass.intM = 444;           // CS0117
    }
}
```

C# Language Specification

- [Modifiers](#)
- [public](#)
- [private](#)
- [protected](#)

private (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `private` keyword is a member access modifier.

This page covers `private` access. The `private` keyword is also part of the `private protected` access modifier.

Private access is the least permissive access level. Private members are accessible only within the body of the class or the struct in which they are declared, as in this example:

```
class Employee
{
    private int _i;
    double _d;    // private access by default
}
```

Nested types in the same body can also access those private members.

It is a compile-time error to reference a private member outside the class or the struct in which it is declared.

For a comparison of `private` with the other access modifiers, see [Accessibility Levels](#) and [Access Modifiers](#).

Example

In this example, the `Employee` class contains two private data members, `_name` and `_salary`. As private members, they cannot be accessed except by member methods. Public methods named `GetName` and `Salary` are added to allow controlled access to the private members. The `_name` member is accessed by way of a public method, and the `_salary` member is accessed by way of a public read-only property. (See [Properties](#) for more information.)

```

class Employee2
{
    private readonly string _name = "FirstName, LastName";
    private readonly double _salary = 100.0;

    public string GetName()
    {
        return _name;
    }

    public double Salary
    {
        get { return _salary; }
    }
}

class PrivateTest
{
    static void Main()
    {
        var e = new Employee2();

        // The data members are inaccessible (private), so
        // they can't be accessed like this:
        //     string n = e._name;
        //     double s = e._salary;

        // '_name' is indirectly accessed via method:
        string n = e.GetName();

        // '_salary' is indirectly accessed via property
        double s = e.Salary;
    }
}

```

C# language specification

For more information, see [Declared accessibility](#) in the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

- [Access Modifiers](#)
- [Accessibility Levels](#)
- [Modifiers](#)
- [public](#)
- [protected](#)
- [internal](#)

protected (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `protected` keyword is a member access modifier.

NOTE

This page covers `protected` access. The `protected` keyword is also part of the `protected internal` and `private protected` access modifiers.

A protected member is accessible within its class and by derived class instances.

For a comparison of `protected` with the other access modifiers, see [Accessibility Levels](#).

Example 1

A protected member of a base class is accessible in a derived class only if the access occurs through the derived class type. For example, consider the following code segment:

```
class A
{
    protected int x = 123;
}

class B : A
{
    static void Main()
    {
        var a = new A();
        var b = new B();

        // Error CS1540, because x can only be accessed by
        // classes derived from A.
        // a.x = 10;

        // OK, because this class derives from A.
        b.x = 10;
    }
}
```

The statement `a.x = 10` generates an error because it is made within the static method `Main`, and not an instance of class `B`.

Struct members cannot be protected because the struct cannot be inherited.

Example 2

In this example, the class `DerivedPoint` is derived from `Point`. Therefore, you can access the protected members of the base class directly from the derived class.

```

class Point
{
    protected int x;
    protected int y;
}

class DerivedPoint: Point
{
    static void Main()
    {
        var dpoint = new DerivedPoint();

        // Direct access to protected members.
        dpoint.x = 10;
        dpoint.y = 15;
        Console.WriteLine($"x = {dpoint.x}, y = {dpoint.y}");
    }
}
// Output: x = 10, y = 15

```

If you change the access levels of `x` and `y` to [private](#), the compiler will issue the error messages:

```
'Point.y' is inaccessible due to its protection level.
```

```
'Point.x' is inaccessible due to its protection level.
```

C# language specification

For more information, see [Declared accessibility](#) in the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

See also

- [C# Reference](#)
- [C# Programming Guide](#)

- [Access Modifiers](#)
- [Accessibility Levels](#)
- [Modifiers](#)
- [public](#)
- [private](#)
- [internal](#)
- [Security concerns for internal virtual keywords](#)

public (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `public` keyword is an access modifier for types and type members. Public access is the most permissive access level. There are no restrictions on accessing public members, as in this example:

```
class SampleClass
{
    public int x; // No access restrictions.
}
```

See [Access Modifiers](#) and [Accessibility Levels](#) for more information.

Example

In the following example, two classes are declared, `PointTest` and `Program`. The public members `x` and `y` of `PointTest` are accessed directly from `Program`.

```
class PointTest
{
    public int x;
    public int y;
}

class Program
{
    static void Main()
    {
        var p = new PointTest();
        // Direct access to public members.
        p.x = 10;
        p.y = 15;
        Console.WriteLine($"x = {p.x}, y = {p.y}");
    }
}
// Output: x = 10, y = 15
```

If you change the `public` access level to `private` or `protected`, you will get the error message:

'PointTest.y' is inaccessible due to its protection level.

C# language specification

For more information, see [Declared accessibility](#) in the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

See also

- [C# Reference](#)

- [C# Keywords](#)
- [Access Modifiers](#)

- Accessibility Levels
- Modifiers
- private
- protected
- internal

protected internal (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `protected internal` keyword combination is a member access modifier. A protected internal member is accessible from the current assembly or from types that are derived from the containing class. For a comparison of `protected internal` with the other access modifiers, see [Accessibility Levels](#).

Example

A protected internal member of a base class is accessible from any type within its containing assembly. It is also accessible in a derived class located in another assembly only if the access occurs through a variable of the derived class type. For example, consider the following code segment:

```
// Assembly1.cs
// Compile with: /target:library
public class BaseClass
{
    protected internal int myValue = 0;
}

class TestAccess
{
    void Access()
    {
        var baseObject = new BaseClass();
        baseObject.myValue = 5;
    }
}
```

```
// Assembly2.cs
// Compile with: /reference:Assembly1.dll
class DerivedClass : BaseClass
{
    static void Main()
    {
        var baseObject = new BaseClass();
        var derivedObject = new DerivedClass();

        // Error CS1540, because myValue can only be accessed by
        // classes derived from BaseClass.
        // baseObject.myValue = 10;

        // OK, because this class derives from BaseClass.
        derivedObject.myValue = 10;
    }
}
```

This example contains two files, `Assembly1.cs` and `Assembly2.cs`. The first file contains a public base class, `BaseClass`, and another class, `TestAccess`. `BaseClass` owns a protected internal member, `myValue`, which is accessed by the `TestAccess` type. In the second file, an attempt to access `myValue` through an instance of `BaseClass` will produce an error, while an access to this member through an instance of a derived class, `DerivedClass` will succeed.

Struct members cannot be `protected internal` because the struct cannot be inherited.

C# language specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

See also

- [C# Reference](#)
- [C# Programming Guide](#)
- [C# Keywords](#)
- [Access Modifiers](#)
- [Accessibility Levels](#)
- [Modifiers](#)
- [public](#)
- [private](#)
- [internal](#)
- [Security concerns for internal virtual keywords](#)

private protected (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `private protected` keyword combination is a member access modifier. A private protected member is accessible by types derived from the containing class, but only within its containing assembly. For a comparison of `private protected` with the other access modifiers, see [Accessibility Levels](#).

NOTE

The `private protected` access modifier is valid in C# version 7.2 and later.

Example

A private protected member of a base class is accessible from derived types in its containing assembly only if the static type of the variable is the derived class type. For example, consider the following code segment:

```
public class BaseClass
{
    private protected int myValue = 0;
}

public class DerivedClass1 : BaseClass
{
    void Access()
    {
        var baseObject = new BaseClass();

        // Error CS1540, because myValue can only be accessed by
        // classes derived from BaseClass.
        // baseObject.myValue = 5;

        // OK, accessed through the current derived class instance
        myValue = 5;
    }
}
```

```
// Assembly2.cs
// Compile with: /reference:Assembly1.dll
class DerivedClass2 : BaseClass
{
    void Access()
    {
        // Error CS0122, because myValue can only be
        // accessed by types in Assembly1
        // myValue = 10;
    }
}
```

This example contains two files, `Assembly1.cs` and `Assembly2.cs`. The first file contains a public base class, `BaseClass`, and a type derived from it, `DerivedClass1`. `BaseClass` owns a private protected member, `myValue`, which `DerivedClass1` tries to access in two ways. The first attempt to access `myValue` through an instance of `BaseClass` will produce an error. However, the attempt to use it as an inherited member in `DerivedClass1` will succeed.

In the second file, an attempt to access `myValue` as an inherited member of `DerivedClass2` will produce an error, as it is only accessible by derived types in `Assembly1`.

If `Assembly1.cs` contains an [InternalsVisibleToAttribute](#) that names `Assembly2`, the derived class `DerivedClass2` will have access to `private protected` members declared in `BaseClass`. `InternalsVisibleTo` makes `private protected` members visible to derived classes in other assemblies.

Struct members cannot be `private protected` because the struct cannot be inherited.

C# language specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

- [internal](#)
- [Security concerns for internal virtual keywords](#)

abstract (C# Reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

The `abstract` modifier indicates that the thing being modified has a missing or incomplete implementation. The `abstract` modifier can be used with classes, methods, properties, indexers, and events. Use the `abstract` modifier in a class declaration to indicate that a class is intended only to be a base class of other classes, not instantiated on its own. Members marked as `abstract` must be implemented by non-`abstract` classes that derive from the `abstract` class.

Example 1

In this example, the class `Square` must provide an implementation of `GetArea` because it derives from `Shape`:

```
abstract class Shape
{
    public abstract int GetArea();
}

class Square : Shape
{
    private int _side;

    public Square(int n) => _side = n;

    // GetArea method is required to avoid a compile-time error.
    public override int GetArea() => _side * _side;

    static void Main()
    {
        var sq = new Square(12);
        Console.WriteLine($"Area of the square = {sq.GetArea()}");
    }
}

// Output: Area of the square = 144
```

Abstract classes have the following features:

- An `abstract` class cannot be instantiated.
- An `abstract` class may contain `abstract` methods and accessors.
- It is not possible to modify an `abstract` class with the `sealed` modifier because the two modifiers have opposite meanings. The `sealed` modifier prevents a class from being inherited and the `abstract` modifier requires a class to be inherited.
- A non-`abstract` class derived from an `abstract` class must include actual implementations of all inherited `abstract` methods and accessors.

Use the `abstract` modifier in a method or property declaration to indicate that the method or property does not contain implementation.

`Abstract` methods have the following features:

- An `abstract` method is implicitly a virtual method.
- `Abstract` method declarations are only permitted in `abstract` classes.

- Because an abstract method declaration provides no actual implementation, there is no method body; the method declaration simply ends with a semicolon and there are no curly braces ({ }) following the signature. For example:

```
public abstract void MyMethod();
```

The implementation is provided by a method [override](#), which is a member of a non-abstract class.

- It is an error to use the [static](#) or [virtual](#) modifiers in an abstract method declaration.

Abstract properties behave like abstract methods, except for the differences in declaration and invocation syntax.

- It is an error to use the `abstract` modifier on a static property.
- An abstract inherited property can be overridden in a derived class by including a property declaration that uses the [override](#) modifier.

For more information about abstract classes, see [Abstract and Sealed Classes and Class Members](#).

An abstract class must provide implementation for all interface members.

An abstract class that implements an interface might map the interface methods onto abstract methods. For example:

```
interface I
{
    void M();
}

abstract class C : I
{
    public abstract void M();
}
```

Example 2

In this example, the class `DerivedClass` is derived from an abstract class `BaseClass`. The abstract class contains an abstract method, `AbstractMethod`, and two abstract properties, `x` and `y`.

```
// Abstract class
abstract class BaseClass
{
    protected int _x = 100;
    protected int _y = 150;

    // Abstract method
    public abstract void AbstractMethod();

    // Abstract properties
    public abstract int X { get; }
    public abstract int Y { get; }
}

class DerivedClass : BaseClass
{
    public override void AbstractMethod()
    {
        _x++;
        _y++;
    }

    public override int X    // overriding property
    {
        get
        {
            return _x + 10;
        }
    }

    public override int Y    // overriding property
    {
        get
        {
            return _y + 10;
        }
    }

    static void Main()
    {
        var o = new DerivedClass();
        o.AbstractMethod();
        Console.WriteLine($"x = {o.X}, y = {o.Y}");
    }
}
// Output: x = 111, y = 161
```

In the preceding example, if you attempt to instantiate the abstract class by using a statement like this:

```
BaseClass bc = new BaseClass();    // Error
```

You will get an error saying that the compiler cannot create an instance of the abstract class 'BaseClass'.

C# Language Specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

See also

- [C# Reference](#)
- [C# Programming Guide](#)

- [Modifiers](#)
- [virtual](#)
- [override](#)
- [C# Keywords](#)

async (C# Reference)

12/28/2021 • 4 minutes to read • [Edit Online](#)

Use the `async` modifier to specify that a method, [lambda expression](#), or [anonymous method](#) is asynchronous. If you use this modifier on a method or expression, it's referred to as an *async method*. The following example defines an async method named `ExampleMethodAsync`:

```
public async Task<int> ExampleMethodAsync()
{
    //...
}
```

If you're new to asynchronous programming or do not understand how an async method uses the `await` operator to do potentially long-running work without blocking the caller's thread, read the introduction in [Asynchronous programming with async and await](#). The following code is found inside an async method and calls the `HttpClient.GetStringAsync` method:

```
string contents = await httpClient.GetStringAsync(requestUrl);
```

An async method runs synchronously until it reaches its first `await` expression, at which point the method is suspended until the awaited task is complete. In the meantime, control returns to the caller of the method, as the example in the next section shows.

If the method that the `async` keyword modifies doesn't contain an `await` expression or statement, the method executes synchronously. A compiler warning alerts you to any async methods that don't contain `await` statements, because that situation might indicate an error. See [Compiler Warning \(level 1\) CS4014](#).

The `async` keyword is contextual in that it's a keyword only when it modifies a method, a lambda expression, or an anonymous method. In all other contexts, it's interpreted as an identifier.

Example

The following example shows the structure and flow of control between an async event handler, `StartButton_Click`, and an async method, `ExampleMethodAsync`. The result from the async method is the number of characters of a web page. The code is suitable for a Windows Presentation Foundation (WPF) app or Windows Store app that you create in Visual Studio; see the code comments for setting up the app.

You can run this code in Visual Studio as a Windows Presentation Foundation (WPF) app or a Windows Store app. You need a Button control named `StartButton` and a Textbox control named `ResultsTextBox`. Remember to set the names and handler so that you have something like this:

```
<Button Content="Button" HorizontalAlignment="Left" Margin="88,77,0,0" VerticalAlignment="Top" Width="75"
        Click="StartButton_Click" Name="StartButton"/>
<TextBox HorizontalAlignment="Left" Height="137" Margin="88,140,0,0" TextWrapping="Wrap"
        Text="&lt;Enter a URL&gt;" VerticalAlignment="Top" Width="310" Name="ResultsTextBox"/>
```

To run the code as a WPF app:

- Paste this code into the `MainWindow` class in `MainWindow.xaml.cs`.
- Add a reference to `System.Net.Http`.

- Add a `using` directive for `System.Net.Http`.

To run the code as a Windows Store app:

- Paste this code into the `MainPage` class in `MainPage.xaml.cs`.
- Add using directives for `System.Net.Http` and `System.Threading.Tasks`.

```
private async void StartButton_Click(object sender, RoutedEventArgs e)
{
    // ExampleMethodAsync returns a Task<int>, which means that the method
    // eventually produces an int result. However, ExampleMethodAsync returns
    // the Task<int> value as soon as it reaches an await.
    ResultsTextBox.Text += "\n";

    try
    {
        int length = await ExampleMethodAsync();
        // Note that you could put "await ExampleMethodAsync()" in the next line where
        // "length" is, but due to when '+= ' fetches the value of ResultsTextBox, you
        // would not see the global side effect of ExampleMethodAsync setting the text.
        ResultsTextBox.Text += String.Format("Length: {0:N0}\n", length);
    }
    catch (Exception)
    {
        // Process the exception if one occurs.
    }
}

public async Task<int> ExampleMethodAsync()
{
    var httpClient = new HttpClient();
    int exampleInt = (await httpClient.GetStringAsync("http://msdn.microsoft.com")).Length;
    ResultsTextBox.Text += "Preparing to finish ExampleMethodAsync.\n";
    // After the following return statement, any method that's awaiting
    // ExampleMethodAsync (in this case, StartButton_Click) can get the
    // integer result.
    return exampleInt;
}

// The example displays the following output:
// Preparing to finish ExampleMethodAsync.
// Length: 53292
```

IMPORTANT

For more information about tasks and the code that executes while waiting for a task, see [Asynchronous programming with async and await](#). For a full console example that uses similar elements, see [Process asynchronous tasks as they complete \(C#\)](#).

Return Types

An async method can have the following return types:

- [Task](#)
- [Task<TResult>](#)
- **void.** `async void` methods are generally discouraged for code other than event handlers because callers cannot `await` those methods and must implement a different mechanism to report successful completion or error conditions.
- Starting with C# 7.0, any type that has an accessible `GetAwaiter` method. The `System.Threading.Tasks.ValueTask<TResult>` type is one such implementation. It is available by adding the

NuGet package `System.Threading.Tasks.Extensions`.

The async method can't declare any [in](#), [ref](#) or [out](#) parameters, nor can it have a [reference return value](#), but it can call methods that have such parameters.

You specify `Task<TResult>` as the return type of an async method if the [return](#) statement of the method specifies an operand of type `TResult`. You use `Task` if no meaningful value is returned when the method is completed. That is, a call to the method returns a `Task`, but when the `Task` is completed, any `await` expression that's awaiting the `Task` evaluates to `void`.

You use the `void` return type primarily to define event handlers, which require that return type. The caller of a `void`-returning async method can't await it and can't catch exceptions that the method throws.

Starting with C# 7.0, you return another type, typically a value type, that has a `GetAwaiter` method to minimize memory allocations in performance-critical sections of code.

For more information and examples, see [Async Return Types](#).

const (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

You use the `const` keyword to declare a constant field or a constant local. Constant fields and locals aren't variables and may not be modified. Constants can be numbers, Boolean values, strings, or a null reference. Don't create a constant to represent information that you expect to change at any time. For example, don't use a constant field to store the price of a service, a product version number, or the brand name of a company. These values can change over time, and because compilers propagate constants, other code compiled with your libraries will have to be recompiled to see the changes. See also the [readonly](#) keyword. For example:

```
const int X = 0;
public const double GravitationalConstant = 6.673e-11;
private const string ProductName = "Visual C#";
```

Beginning with C# 10, [interpolated strings](#) may be constants, if all expressions used are also constant strings. This feature can improve the code that builds constant strings:

```
const string Language = "C#";
const string Platform = ".NET";
const string Version = "10.0";
const string FullProductName = $"{Platform} - Language: {Language} Version: {Version}";
```

Remarks

The type of a constant declaration specifies the type of the members that the declaration introduces. The initializer of a constant local or a constant field must be a constant expression that can be implicitly converted to the target type.

A constant expression is an expression that can be fully evaluated at compile time. Therefore, the only possible values for constants of reference types are `string` and a null reference.

The constant declaration can declare multiple constants, such as:

```
public const double X = 1.0, Y = 2.0, Z = 3.0;
```

The `static` modifier is not allowed in a constant declaration.

A constant can participate in a constant expression, as follows:

```
public const int C1 = 5;
public const int C2 = C1 + 100;
```

NOTE

The `readonly` keyword differs from the `const` keyword. A `const` field can only be initialized at the declaration of the field. A `readonly` field can be initialized either at the declaration or in a constructor. Therefore, `readonly` fields can have different values depending on the constructor used. Also, although a `const` field is a compile-time constant, the `readonly` field can be used for run-time constants, as in this line:

```
public static readonly uint l1 = (uint)DateTime.Now.Ticks;
```

Examples

```
public class ConstTest
{
    class SampleClass
    {
        public int x;
        public int y;
        public const int C1 = 5;
        public const int C2 = C1 + 5;

        public SampleClass(int p1, int p2)
        {
            x = p1;
            y = p2;
        }
    }

    static void Main()
    {
        var mC = new SampleClass(11, 22);
        Console.WriteLine($"x = {mC.x}, y = {mC.y}");
        Console.WriteLine($"C1 = {SampleClass.C1}, C2 = {SampleClass.C2}");
    }
}

/* Output
x = 11, y = 22
C1 = 5, C2 = 10
*/
```

This example demonstrates how to use constants as local variables.

```
public class SealedTest
{
    static void Main()
    {
        const int C = 707;
        Console.WriteLine($"My local constant = {C}");
    }
}

// Output: My local constant = 707
```

- [readonly](#)

event (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `event` keyword is used to declare an event in a publisher class.

Example

The following example shows how to declare and raise an event that uses [EventHandler](#) as the underlying delegate type. For the complete code example that also shows how to use the generic [EventHandler<TEventArgs>](#) delegate type and how to subscribe to an event and create an event handler method, see [How to publish events that conform to .NET Guidelines](#).

```
public class SampleEventArgs
{
    public SampleEventArgs(string text) { Text = text; }
    public string Text { get; } // readonly
}

public class Publisher
{
    // Declare the delegate (if using non-generic pattern).
    public delegate void SampleEventHandler(object sender, SampleEventArgs e);

    // Declare the event.
    public event SampleEventHandler SampleEvent;

    // Wrap the event in a protected virtual method
    // to enable derived classes to raise the event.
    protected virtual void RaiseSampleEvent()
    {
        // Raise the event in a thread-safe manner using the ?. operator.
        SampleEvent?.Invoke(this, new SampleEventArgs("Hello"));
    }
}
```

Events are a special kind of multicast delegate that can only be invoked from within the class or struct where they are declared (the publisher class). If other classes or structs subscribe to the event, their event handler methods will be called when the publisher class raises the event. For more information and code examples, see [Events](#) and [Delegates](#).

Events can be marked as [public](#), [private](#), [protected](#), [internal](#), [protected internal](#), or [private protected](#). These access modifiers define how users of the class can access the event. For more information, see [Access Modifiers](#).

Keywords and events

The following keywords apply to events.

KEYWORD	DESCRIPTION	FOR MORE INFORMATION
static	Makes the event available to callers at any time, even if no instance of the class exists.	Static Classes and Static Class Members

KEYWORD	DESCRIPTION	FOR MORE INFORMATION
virtual	Allows derived classes to override the event behavior by using the override keyword.	Inheritance
sealed	Specifies that for derived classes it is no longer virtual.	
abstract	The compiler will not generate the <code>add</code> and <code>remove</code> event accessor blocks and therefore derived classes must provide their own implementation.	

An event may be declared as a static event by using the [static](#) keyword. This makes the event available to callers at any time, even if no instance of the class exists. For more information, see [Static Classes and Static Class Members](#).

An event can be marked as a virtual event by using the [virtual](#) keyword. This enables derived classes to override the event behavior by using the [override](#) keyword. For more information, see [Inheritance](#). An event overriding a virtual event can also be [sealed](#), which specifies that for derived classes it is no longer virtual. Lastly, an event can be declared [abstract](#), which means that the compiler will not generate the `add` and `remove` event accessor blocks. Therefore derived classes must provide their own implementation.

C# language specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

See also

- [remove](#)
- [Modifiers](#)
- [How to combine delegates \(Multicast Delegates\)](#)

extern (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `extern` modifier is used to declare a method that is implemented externally. A common use of the `extern` modifier is with the `DllImport` attribute when you are using Interop services to call into unmanaged code. In this case, the method must also be declared as `static`, as shown in the following example:

```
[DllImport("avifil32.dll")]
private static extern void AVIFileInit();
```

The `extern` keyword can also define an external assembly alias, which makes it possible to reference different versions of the same component from within a single assembly. For more information, see [extern alias](#).

It is an error to use the `abstract` and `extern` modifiers together to modify the same member. Using the `extern` modifier means that the method is implemented outside the C# code, whereas using the `abstract` modifier means that the method implementation is not provided in the class.

The `extern` keyword has more limited uses in C# than in C++. To compare the C# keyword with the C++ keyword, see [Using extern to Specify Linkage in the C++ Language Reference](#).

Example 1

In this example, the program receives a string from the user and displays it inside a message box. The program uses the `MessageBox` method imported from the `User32.dll` library.

```
//using System.Runtime.InteropServices;
class ExternTest
{
    [DllImport("User32.dll", CharSet=CharSet.Unicode)]
    public static extern int MessageBox(IntPtr h, string m, string c, int type);

    static int Main()
    {
        string myString;
        Console.WriteLine("Enter your message: ");
        myString = Console.ReadLine();
        return MessageBox((IntPtr)0, myString, "My Message Box", 0);
    }
}
```

Example 2

This example illustrates a C# program that calls into a C library (a native DLL).

1. Create the following C file and name it `cmdll.c`:

```
// cmdll.c
// Compile with: -LD
int __declspec(dllexport) SampleMethod(int i)
{
    return i*10;
}
```

2. Open a Visual Studio x64 (or x32) Native Tools Command Prompt window from the Visual Studio installation directory and compile the `cmdll.c` file by typing `cl -LD cmdll.c` at the command prompt.
3. In the same directory, create the following C# file and name it `cm.cs` :

```
// cm.cs
using System;
using System.Runtime.InteropServices;
public class MainClass
{
    [DllImport("Cmdll.dll")]
    public static extern int SampleMethod(int x);

    static void Main()
    {
        Console.WriteLine("SampleMethod() returns {0}.", SampleMethod(5));
    }
}
```

4. Open a Visual Studio x64 (or x32) Native Tools Command Prompt window from the Visual Studio installation directory and compile the `cm.cs` file by typing:

```
csc cm.cs (for the x64 command prompt) —or— csc -platform:x86 cm.cs (for the x32 command prompt)
```

This will create the executable file `cm.exe` .

5. Run `cm.exe` . The `SampleMethod` method passes the value 5 to the DLL file, which returns the value multiplied by 10. The program produces the following output:

```
SampleMethod() returns 50.
```

C# language specification

in (Generic Modifier) (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

For generic type parameters, the `in` keyword specifies that the type parameter is contravariant. You can use the `in` keyword in generic interfaces and delegates.

Contravariance enables you to use a less derived type than that specified by the generic parameter. This allows for implicit conversion of classes that implement contravariant interfaces and implicit conversion of delegate types. Covariance and contravariance in generic type parameters are supported for reference types, but they are not supported for value types.

A type can be declared contravariant in a generic interface or delegate only if it defines the type of a method's parameters and not of a method's return type. `In`, `ref`, and `out` parameters must be invariant, meaning they are neither covariant or contravariant.

An interface that has a contravariant type parameter allows its methods to accept arguments of less derived types than those specified by the interface type parameter. For example, in the `IComparer<T>` interface, type `T` is contravariant, you can assign an object of the `IComparer<Person>` type to an object of the `IComparer<Employee>` type without using any special conversion methods if `Employee` inherits `Person`.

A contravariant delegate can be assigned another delegate of the same type, but with a less derived generic type parameter.

For more information, see [Covariance and Contravariance](#).

Contravariant generic interface

The following example shows how to declare, extend, and implement a contravariant generic interface. It also shows how you can use implicit conversion for classes that implement this interface.

```
// Contravariant interface.
interface IContravariant<in A> { }

// Extending contravariant interface.
interface IExtContravariant<in A> : IContravariant<A> { }

// Implementing contravariant interface.
class Sample<A> : IContravariant<A> { }

class Program
{
    static void Test()
    {
        IContravariant<Object> iobj = new Sample<Object>();
        IContravariant<String> istr = new Sample<String>();

        // You can assign iobj to istr because
        // the IContravariant interface is contravariant.
        istr = iobj;
    }
}
```

Contravariant generic delegate

The following example shows how to declare, instantiate, and invoke a contravariant generic delegate. It also

shows how you can implicitly convert a delegate type.

```
// Contravariant delegate.
public delegate void DContravariant<in A>(A argument);

// Methods that match the delegate signature.
public static void SampleControl(Control control)
{ }
public static void SampleButton(Button button)
{ }

public void Test()
{

    // Instantiating the delegates with the methods.
    DContravariant<Control> dControl = SampleControl;
    DContravariant<Button> dButton = SampleButton;

    // You can assign dControl to dButton
    // because the DContravariant delegate is contravariant.
    dButton = dControl;

    // Invoke the delegate.
    dButton(new Button());
}
```

C# language specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

See also

- [out](#)
- [Covariance and Contravariance](#)
- [Modifiers](#)

new modifier (C# Reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

When used as a declaration modifier, the `new` keyword explicitly hides a member that is inherited from a base class. When you hide an inherited member, the derived version of the member replaces the base class version. This assumes that the base class version of the member is visible, as it would already be hidden if it were marked as `private` or, in some cases, `internal`. Although you can hide `public` or `protected` members without using the `new` modifier, you get a compiler warning. If you use `new` to explicitly hide a member, it suppresses this warning.

You can also use the `new` keyword to [create an instance of a type](#) or as a [generic type constraint](#).

To hide an inherited member, declare it in the derived class by using the same member name, and modify it with the `new` keyword. For example:

```
public class BaseC
{
    public int x;
    public void Invoke() { }
}
public class DerivedC : BaseC
{
    new public void Invoke() { }
}
```

In this example, `BaseC.Invoke` is hidden by `DerivedC.Invoke`. The field `x` is not affected because it is not hidden by a similar name.

Name hiding through inheritance takes one of the following forms:

- Generally, a constant, field, property, or type that is introduced in a class or struct hides all base class members that share its name. There are special cases. For example, if you declare a new field with name `N` to have a type that is not invocable, and a base type declares `N` to be a method, the new field does not hide the base declaration in invocation syntax. For more information, see the [Member lookup](#) section of the [C# language specification](#).
- A method introduced in a class or struct hides properties, fields, and types that share that name in the base class. It also hides all base class methods that have the same signature.
- An indexer introduced in a class or struct hides all base class indexers that have the same signature.

It is an error to use both `new` and `override` on the same member, because the two modifiers have mutually exclusive meanings. The `new` modifier creates a new member with the same name and causes the original member to become hidden. The `override` modifier extends the implementation for an inherited member.

Using the `new` modifier in a declaration that does not hide an inherited member generates a warning.

Examples

In this example, a base class, `BaseC`, and a derived class, `DerivedC`, use the same field name `x`, which hides the value of the inherited field. The example demonstrates the use of the `new` modifier. It also demonstrates how to access the hidden members of the base class by using their fully qualified names.

```

public class BaseC
{
    public static int x = 55;
    public static int y = 22;
}

public class DerivedC : BaseC
{
    // Hide field 'x'.
    new public static int x = 100;

    static void Main()
    {
        // Display the new value of x:
        Console.WriteLine(x);

        // Display the hidden value of x:
        Console.WriteLine(BaseC.x);

        // Display the unhidden member y:
        Console.WriteLine(y);
    }
}
/*
Output:
100
55
22
*/

```

In this example, a nested class hides a class that has the same name in the base class. The example demonstrates how to use the `new` modifier to eliminate the warning message and how to access the hidden class members by using their fully qualified names.

```

public class BaseC
{
    public class NestedC
    {
        public int x = 200;
        public int y;
    }
}

public class DerivedC : BaseC
{
    // Nested type hiding the base type members.
    new public class NestedC
    {
        public int x = 100;
        public int y;
        public int z;
    }

    static void Main()
    {
        // Creating an object from the overlapping class:
        NestedC c1 = new NestedC();

        // Creating an object from the hidden class:
        BaseC.NestedC c2 = new BaseC.NestedC();

        Console.WriteLine(c1.x);
        Console.WriteLine(c2.x);
    }
}
/*
Output:
100
200
*/

```

If you remove the `new` modifier, the program will still compile and run, but you will get the following warning:

The keyword `new` is required on 'MyDerivedC.x' because it hides inherited member 'MyBaseC.x'.

C# language specification

For more information, see [The new modifier](#) section of the [C# language specification](#).

See also

- [C# Reference](#)
- [C# Programming Guide](#)
- [C# Keywords](#)
- [Modifiers](#)
- [Versioning with the Override and New Keywords](#)
- [Knowing When to Use Override and New Keywords](#)

out (generic modifier) (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

For generic type parameters, the `out` keyword specifies that the type parameter is covariant. You can use the `out` keyword in generic interfaces and delegates.

Covariance enables you to use a more derived type than that specified by the generic parameter. This allows for implicit conversion of classes that implement covariant interfaces and implicit conversion of delegate types. Covariance and contravariance are supported for reference types, but they are not supported for value types.

An interface that has a covariant type parameter enables its methods to return more derived types than those specified by the type parameter. For example, because in .NET Framework 4, in `IEnumerable<T>`, type `T` is covariant, you can assign an object of the `IEnumerable(Of String)` type to an object of the `IEnumerable(Of Object)` type without using any special conversion methods.

A covariant delegate can be assigned another delegate of the same type, but with a more derived generic type parameter.

For more information, see [Covariance and Contravariance](#).

Example - covariant generic interface

The following example shows how to declare, extend, and implement a covariant generic interface. It also shows how to use implicit conversion for classes that implement a covariant interface.

```
// Covariant interface.
interface ICovariant<out R> { }

// Extending covariant interface.
interface IExtCovariant<out R> : ICovariant<R> { }

// Implementing covariant interface.
class Sample<R> : ICovariant<R> { }

class Program
{
    static void Test()
    {
        ICovariant<Object> iobj = new Sample<Object>();
        ICovariant<String> istr = new Sample<String>();

        // You can assign istr to iobj because
        // the ICovariant interface is covariant.
        iobj = istr;
    }
}
```

In a generic interface, a type parameter can be declared covariant if it satisfies the following conditions:

- The type parameter is used only as a return type of interface methods and not used as a type of method arguments.

NOTE

There is one exception to this rule. If in a covariant interface you have a contravariant generic delegate as a method parameter, you can use the covariant type as a generic type parameter for this delegate. For more information about covariant and contravariant generic delegates, see [Variance in Delegates](#) and [Using Variance for Func and Action Generic Delegates](#).

- The type parameter is not used as a generic constraint for the interface methods.

Example - covariant generic delegate

The following example shows how to declare, instantiate, and invoke a covariant generic delegate. It also shows how to implicitly convert delegate types.

```
// Covariant delegate.
public delegate R DCovariant<out R>();

// Methods that match the delegate signature.
public static Control SampleControl()
{ return new Control(); }

public static Button SampleButton()
{ return new Button(); }

public void Test()
{
    // Instantiate the delegates with the methods.
    DCovariant<Control> dControl = SampleControl;
    DCovariant<Button> dButton = SampleButton;

    // You can assign dButton to dControl
    // because the DCovariant delegate is covariant.
    dControl = dButton;

    // Invoke the delegate.
    dControl();
}
```

In a generic delegate, a type can be declared covariant if it is used only as a method return type and not used for method arguments.

C# language specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

See also

- [Variance in Generic Interfaces](#)
- [in](#)
- [Modifiers](#)

override (C# reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

The `override` modifier is required to extend or modify the abstract or virtual implementation of an inherited method, property, indexer, or event.

In the following example, the `Square` class must provide an overridden implementation of `GetArea` because `GetArea` is inherited from the abstract `Shape` class:

```
abstract class Shape
{
    public abstract int GetArea();
}

class Square : Shape
{
    private int _side;

    public Square(int n) => _side = n;

    // GetArea method is required to avoid a compile-time error.
    public override int GetArea() => _side * _side;

    static void Main()
    {
        var sq = new Square(12);
        Console.WriteLine($"Area of the square = {sq.GetArea()}");
    }
}
// Output: Area of the square = 144
```

An `override` method provides a new implementation of the method inherited from a base class. The method that is overridden by an `override` declaration is known as the overridden base method. An `override` method must have the same signature as the overridden base method. Beginning with C# 9.0, `override` methods support covariant return types. In particular, the return type of an `override` method can derive from the return type of the corresponding base method. In C# 8.0 and earlier, the return types of an `override` method and the overridden base method must be the same.

You cannot override a non-virtual or static method. The overridden base method must be `virtual`, `abstract`, or `override`.

An `override` declaration cannot change the accessibility of the `virtual` method. Both the `override` method and the `virtual` method must have the same [access level modifier](#).

You cannot use the `new`, `static`, or `virtual` modifiers to modify an `override` method.

An overriding property declaration must specify exactly the same access modifier, type, and name as the inherited property. Beginning with C# 9.0, read-only overriding properties support covariant return types. The overridden property must be `virtual`, `abstract`, or `override`.

For more information about how to use the `override` keyword, see [Versioning with the Override and New Keywords](#) and [Knowing when to use Override and New Keywords](#). For information about inheritance, see [Inheritance](#).

Example

This example defines a base class named `Employee`, and a derived class named `SalesEmployee`. The `SalesEmployee` class includes an extra field, `salesbonus`, and overrides the method `CalculatePay` in order to take it into account.

```

class TestOverride
{
    public class Employee
    {
        public string Name { get; }

        // Basepay is defined as protected, so that it may be
        // accessed only by this class and derived classes.
        protected decimal _basepay;

        // Constructor to set the name and basepay values.
        public Employee(string name, decimal basepay)
        {
            Name = name;
            _basepay = basepay;
        }

        // Declared virtual so it can be overridden.
        public virtual decimal CalculatePay()
        {
            return _basepay;
        }
    }

    // Derive a new class from Employee.
    public class SalesEmployee : Employee
    {
        // New field that will affect the base pay.
        private decimal _salesbonus;

        // The constructor calls the base-class version, and
        // initializes the salesbonus field.
        public SalesEmployee(string name, decimal basepay, decimal salesbonus)
            : base(name, basepay)
        {
            _salesbonus = salesbonus;
        }

        // Override the CalculatePay method
        // to take bonus into account.
        public override decimal CalculatePay()
        {
            return _basepay + _salesbonus;
        }
    }

    static void Main()
    {
        // Create some new employees.
        var employee1 = new SalesEmployee("Alice", 1000, 500);
        var employee2 = new Employee("Bob", 1200);

        Console.WriteLine($"Employee1 {employee1.Name} earned: {employee1.CalculatePay()}");
        Console.WriteLine($"Employee2 {employee2.Name} earned: {employee2.CalculatePay()}");
    }
}
/*
Output:
Employee1 Alice earned: 1500
Employee2 Bob earned: 1200
*/

```

readonly (C# Reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

The `readonly` keyword is a modifier that can be used in four contexts:

- In a [field declaration](#), `readonly` indicates that assignment to the field can only occur as part of the declaration or in a constructor in the same class. A readonly field can be assigned and reassigned multiple times within the field declaration and constructor.

A `readonly` field can't be assigned after the constructor exits. This rule has different implications for value types and reference types:

- Because value types directly contain their data, a field that is a `readonly` value type is immutable.
- Because reference types contain a reference to their data, a field that is a `readonly` reference type must always refer to the same object. That object isn't immutable. The `readonly` modifier prevents the field from being replaced by a different instance of the reference type. However, the modifier doesn't prevent the instance data of the field from being modified through the read-only field.

WARNING

An externally visible type that contains an externally visible read-only field that is a mutable reference type may be a security vulnerability and may trigger warning CA2104 : "Do not declare read only mutable reference types."

- In a `readonly struct` type definition, `readonly` indicates that the structure type is immutable. For more information, see the [readonly struct](#) section of the [Structure types](#) article.
- In an instance member declaration within a structure type, `readonly` indicates that an instance member doesn't modify the state of the structure. For more information, see the [readonly instance members](#) section of the [Structure types](#) article.
- In a [ref readonly method return](#), the `readonly` modifier indicates that method returns a reference and writes aren't allowed to that reference.

The `readonly struct` and `ref readonly` contexts were added in C# 7.2. `readonly` struct members were added in C# 8.0

Readonly field example

In this example, the value of the field `year` can't be changed in the method `ChangeYear`, even though it's assigned a value in the class constructor:

```
class Age
{
    private readonly int _year;
    Age(int year)
    {
        _year = year;
    }
    void ChangeYear()
    {
        //_year = 1967; // Compile error if uncommented.
    }
}
```

You can assign a value to a `readonly` field only in the following contexts:

- When the variable is initialized in the declaration, for example:

```
public readonly int y = 5;
```

- In an instance constructor of the class that contains the instance field declaration.
- In the static constructor of the class that contains the static field declaration.

These constructor contexts are also the only contexts in which it's valid to pass a `readonly` field as an [out](#) or [ref](#) parameter.

NOTE

The `readonly` keyword is different from the `const` keyword. A `const` field can only be initialized at the declaration of the field. A `readonly` field can be assigned multiple times in the field declaration and in any constructor. Therefore, `readonly` fields can have different values depending on the constructor used. Also, while a `const` field is a compile-time constant, the `readonly` field can be used for run-time constants as in the following example:

```
public static readonly uint timeStamp = (uint)DateTime.Now.Ticks;
```

```

public class SamplePoint
{
    public int x;
    // Initialize a readonly field
    public readonly int y = 25;
    public readonly int z;

    public SamplePoint()
    {
        // Initialize a readonly instance field
        z = 24;
    }

    public SamplePoint(int p1, int p2, int p3)
    {
        x = p1;
        y = p2;
        z = p3;
    }

    public static void Main()
    {
        SamplePoint p1 = new SamplePoint(11, 21, 32);    // OK
        Console.WriteLine($"p1: x={p1.x}, y={p1.y}, z={p1.z}");
        SamplePoint p2 = new SamplePoint();
        p2.x = 55;    // OK
        Console.WriteLine($"p2: x={p2.x}, y={p2.y}, z={p2.z}");
    }
    /*
    Output:
        p1: x=11, y=21, z=32
        p2: x=55, y=25, z=24
    */
}

```

In the preceding example, if you use a statement like the following example:

```
p2.y = 66;    // Error
```

you'll get the compiler error message:

A readonly field cannot be assigned to (except in a constructor or a variable initializer)

Ref readonly return example

The `readonly` modifier on a `ref return` indicates that the returned reference can't be modified. The following example returns a reference to the origin. It uses the `readonly` modifier to indicate that callers can't modify the origin:

```

private static readonly SamplePoint s_origin = new SamplePoint(0, 0, 0);
public static ref readonly SamplePoint Origin => ref s_origin;

```

The type returned doesn't need to be a `readonly struct`. Any type that can be returned by `ref` can be returned by `ref readonly`.

C# language specification

- [Fields](#)

sealed (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

When applied to a class, the `sealed` modifier prevents other classes from inheriting from it. In the following example, class `B` inherits from class `A`, but no class can inherit from class `B`.

```
class A {}
sealed class B : A {}
```

You can also use the `sealed` modifier on a method or property that overrides a virtual method or property in a base class. This enables you to allow classes to derive from your class and prevent them from overriding specific virtual methods or properties.

Example

In the following example, `Z` inherits from `Y` but `Z` cannot override the virtual function `F` that is declared in `X` and sealed in `Y`.

```
class X
{
    protected virtual void F() { Console.WriteLine("X.F"); }
    protected virtual void F2() { Console.WriteLine("X.F2"); }
}

class Y : X
{
    sealed protected override void F() { Console.WriteLine("Y.F"); }
    protected override void F2() { Console.WriteLine("Y.F2"); }
}

class Z : Y
{
    // Attempting to override F causes compiler error CS0239.
    // protected override void F() { Console.WriteLine("Z.F"); }

    // Overriding F2 is allowed.
    protected override void F2() { Console.WriteLine("Z.F2"); }
}
```

When you define new methods or properties in a class, you can prevent deriving classes from overriding them by not declaring them as `virtual`.

It is an error to use the `abstract` modifier with a sealed class, because an abstract class must be inherited by a class that provides an implementation of the abstract methods or properties.

When applied to a method or property, the `sealed` modifier must always be used with `override`.

Because structs are implicitly sealed, they cannot be inherited.

For more information, see [Inheritance](#).

For more examples, see [Abstract and Sealed Classes and Class Members](#).

```
sealed class SealedClass
{
    public int x;
    public int y;
}

class SealedTest2
{
    static void Main()
    {
        var sc = new SealedClass();
        sc.x = 110;
        sc.y = 150;
        Console.WriteLine($"x = {sc.x}, y = {sc.y}");
    }
}
// Output: x = 110, y = 150
```

In the previous example, you might try to inherit from the sealed class by using the following statement:

```
class MyDerivedC: SealedClass {} // Error
```

The result is an error message:

```
'MyDerivedC': cannot derive from sealed type 'SealedClass'
```

Remarks

To determine whether to seal a class, method, or property, you should generally consider the following two points:

- The potential benefits that deriving classes might gain through the ability to customize your class.
- The potential that deriving classes could modify your classes in such a way that they would no longer work correctly or as expected.

static (C# Reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

This page covers the `static` modifier keyword. The `static` keyword is also part of the `using static` directive.

Use the `static` modifier to declare a static member, which belongs to the type itself rather than to a specific object. The `static` modifier can be used to declare `static` classes. In classes, interfaces, and structs, you may add the `static` modifier to fields, methods, properties, operators, events, and constructors. The `static` modifier can't be used with indexers or finalizers. For more information, see [Static Classes and Static Class Members](#).

Beginning with C# 8.0, you can add the `static` modifier to a [local function](#). A static local function can't capture local variables or instance state.

Beginning with C# 9.0, you can add the `static` modifier to a [lambda expression](#) or [anonymous method](#). A static lambda or anonymous method can't capture local variables or instance state.

Example - static class

The following class is declared as `static` and contains only `static` methods:

```
static class CompanyEmployee
{
    public static void DoSomething() { /*...*/ }
    public static void DoSomethingElse() { /*...*/ }
}
```

A constant or type declaration is implicitly a `static` member. A `static` member can't be referenced through an instance. Instead, it's referenced through the type name. For example, consider the following class:

```
public class MyBaseC
{
    public struct MyStruct
    {
        public static int x = 100;
    }
}
```

To refer to the `static` member `x`, use the fully qualified name, `MyBaseC.MyStruct.x`, unless the member is accessible from the same scope:

```
Console.WriteLine(MyBaseC.MyStruct.x);
```

While an instance of a class contains a separate copy of all instance fields of the class, there's only one copy of each `static` field.

It isn't possible to use `this` to reference `static` methods or property accessors.

If the `static` keyword is applied to a class, all the members of the class must be `static`.

Classes, interfaces, and `static` classes may have `static` constructors. A `static` constructor is called at some point between when the program starts and the class is instantiated.

NOTE

The `static` keyword has more limited uses than in C++. To compare with the C++ keyword, see [Storage classes \(C++\)](#).

To demonstrate `static` members, consider a class that represents a company employee. Assume that the class contains a method to count employees and a field to store the number of employees. Both the method and the field don't belong to any one employee instance. Instead, they belong to the class of employees as a whole. They should be declared as `static` members of the class.

Example - static field and method

This example reads the name and ID of a new employee, increments the employee counter by one, and displays the information for the new employee and the new number of employees. This program reads the current number of employees from the keyboard.

```

public class Employee4
{
    public string id;
    public string name;

    public Employee4()
    {
    }

    public Employee4(string name, string id)
    {
        this.name = name;
        this.id = id;
    }

    public static int employeeCounter;

    public static int AddEmployee()
    {
        return ++employeeCounter;
    }
}

class MainClass : Employee4
{
    static void Main()
    {
        Console.Write("Enter the employee's name: ");
        string name = Console.ReadLine();
        Console.Write("Enter the employee's ID: ");
        string id = Console.ReadLine();

        // Create and configure the employee object.
        Employee4 e = new Employee4(name, id);
        Console.Write("Enter the current number of employees: ");
        string n = Console.ReadLine();
        Employee4.employeeCounter = Int32.Parse(n);
        Employee4.AddEmployee();

        // Display the new information.
        Console.WriteLine($"Name: {e.name}");
        Console.WriteLine($"ID: {e.id}");
        Console.WriteLine($"New Number of Employees: {Employee4.employeeCounter}");
    }
}
/*
Input:
Matthias Berndt
AF643G
15
*
Sample Output:
Enter the employee's name: Matthias Berndt
Enter the employee's ID: AF643G
Enter the current number of employees: 15
Name: Matthias Berndt
ID: AF643G
New Number of Employees: 16
*/

```

Example - static initialization

This example shows that you can initialize a `static` field by using another `static` field that is not yet declared. The results will be undefined until you explicitly assign a value to the `static` field.

```
class Test
{
    static int x = y;
    static int y = 5;

    static void Main()
    {
        Console.WriteLine(Test.x);
        Console.WriteLine(Test.y);

        Test.x = 99;
        Console.WriteLine(Test.x);
    }
}
/*
Output:
    0
    5
    99
*/
```

C# language specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

unsafe (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `unsafe` keyword denotes an unsafe context, which is required for any operation involving pointers. For more information, see [Unsafe Code and Pointers](#).

You can use the `unsafe` modifier in the declaration of a type or a member. The entire textual extent of the type or member is therefore considered an unsafe context. For example, the following is a method declared with the `unsafe` modifier:

```
unsafe static void FastCopy(byte[] src, byte[] dst, int count)
{
    // Unsafe context: can use pointers here.
}
```

The scope of the unsafe context extends from the parameter list to the end of the method, so pointers can also be used in the parameter list:

```
unsafe static void FastCopy ( byte* ps, byte* pd, int count ) {...}
```

You can also use an unsafe block to enable the use of an unsafe code inside this block. For example:

```
unsafe
{
    // Unsafe context: can use pointers here.
}
```

To compile unsafe code, you must specify the [AllowUnsafeBlocks](#) compiler option. Unsafe code is not verifiable by the common language runtime.

Example

```
// compile with: -unsafe
class UnsafeTest
{
    // Unsafe method: takes pointer to int.
    unsafe static void SquarePtrParam(int* p)
    {
        *p *= *p;
    }

    unsafe static void Main()
    {
        int i = 5;
        // Unsafe method: uses address-of operator (&).
        SquarePtrParam(&i);
        Console.WriteLine(i);
    }
}
// Output: 25
```

C# language specification

For more information, see [Unsafe code](#) in the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

virtual (C# Reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

The `virtual` keyword is used to modify a method, property, indexer, or event declaration and allow for it to be overridden in a derived class. For example, this method can be overridden by any class that inherits it:

```
public virtual double Area()
{
    return x * y;
}
```

The implementation of a virtual member can be changed by an [overriding member](#) in a derived class. For more information about how to use the `virtual` keyword, see [Versioning with the Override and New Keywords](#) and [Knowing When to Use Override and New Keywords](#).

Remarks

When a virtual method is invoked, the run-time type of the object is checked for an overriding member. The overriding member in the most derived class is called, which might be the original member, if no derived class has overridden the member.

By default, methods are non-virtual. You cannot override a non-virtual method.

You cannot use the `virtual` modifier with the `static`, `abstract`, `private`, or `override` modifiers. The following example shows a virtual property:

```

class MyBaseClass
{
    // virtual auto-implemented property. Overrides can only
    // provide specialized behavior if they implement get and set accessors.
    public virtual string Name { get; set; }

    // ordinary virtual property with backing field
    private int _num;
    public virtual int Number
    {
        get { return _num; }
        set { _num = value; }
    }
}

class MyDerivedClass : MyBaseClass
{
    private string _name;

    // Override auto-implemented property with ordinary property
    // to provide specialized accessor behavior.
    public override string Name
    {
        get
        {
            return _name;
        }
        set
        {
            if (!string.IsNullOrEmpty(value))
            {
                _name = value;
            }
            else
            {
                _name = "Unknown";
            }
        }
    }
}

```

Virtual properties behave like virtual methods, except for the differences in declaration and invocation syntax.

- It is an error to use the `virtual` modifier on a static property.
- A virtual inherited property can be overridden in a derived class by including a property declaration that uses the `override` modifier.

Example

In this example, the `Shape` class contains the two coordinates `x`, `y`, and the `Area()` virtual method. Different shape classes such as `Circle`, `Cylinder`, and `Sphere` inherit the `Shape` class, and the surface area is calculated for each figure. Each derived class has its own override implementation of `Area()`.

Notice that the inherited classes `Circle`, `Sphere`, and `Cylinder` all use constructors that initialize the base class, as shown in the following declaration.

```

public Cylinder(double r, double h): base(r, h) {}

```

The following program calculates and displays the appropriate area for each figure by invoking the appropriate implementation of the `Area()` method, according to the object that is associated with the method.

```

class TestClass
{
    public class Shape
    {
        public const double PI = Math.PI;
        protected double _x, _y;

        public Shape()
        {
        }

        public Shape(double x, double y)
        {
            _x = x;
            _y = y;
        }

        public virtual double Area()
        {
            return _x * _y;
        }
    }

    public class Circle : Shape
    {
        public Circle(double r) : base(r, 0)
        {
        }

        public override double Area()
        {
            return PI * _x * _x;
        }
    }

    public class Sphere : Shape
    {
        public Sphere(double r) : base(r, 0)
        {
        }

        public override double Area()
        {
            return 4 * PI * _x * _x;
        }
    }

    public class Cylinder : Shape
    {
        public Cylinder(double r, double h) : base(r, h)
        {
        }

        public override double Area()
        {
            return 2 * PI * _x * _x + 2 * PI * _x * _y;
        }
    }

    static void Main()
    {
        double r = 3.0, h = 5.0;
        Shape c = new Circle(r);
        Shape s = new Sphere(r);
        Shape l = new Cylinder(r, h);
        // Display results.
        Console.WriteLine("Area of Circle    = {0:F2}", c.Area());
        Console.WriteLine("Area of Sphere    = {0:F2}", s.Area());
    }
}

```

```
        Console.WriteLine("Area of Cylinder = {0:F2}", l.Area());
    }
}
/*
Output:
Area of Circle   = 28.27
Area of Sphere   = 113.10
Area of Cylinder = 150.80
*/
```

C# language specification

- [new \(modifier\)](#)

volatile (C# Reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

The `volatile` keyword indicates that a field might be modified by multiple threads that are executing at the same time. The compiler, the runtime system, and even hardware may rearrange reads and writes to memory locations for performance reasons. Fields that are declared `volatile` are excluded from certain kinds of optimizations. There is no guarantee of a single total ordering of volatile writes as seen from all threads of execution. For more information, see the [Volatile](#) class.

NOTE

On a multiprocessor system, a volatile read operation does not guarantee to obtain the latest value written to that memory location by any processor. Similarly, a volatile write operation does not guarantee that the value written would be immediately visible to other processors.

The `volatile` keyword can be applied to fields of these types:

- Reference types.
- Pointer types (in an unsafe context). Note that although the pointer itself can be volatile, the object that it points to cannot. In other words, you cannot declare a "pointer to volatile."
- Simple types such as `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `char`, `float`, and `bool`.
- An `enum` type with one of the following base types: `byte`, `sbyte`, `short`, `ushort`, `int`, or `uint`.
- Generic type parameters known to be reference types.
- [IntPtr](#) and [UIntPtr](#).

Other types, including `double` and `long`, cannot be marked `volatile` because reads and writes to fields of those types cannot be guaranteed to be atomic. To protect multi-threaded access to those types of fields, use the [Interlocked](#) class members or protect access using the `lock` statement.

The `volatile` keyword can only be applied to fields of a `class` or `struct`. Local variables cannot be declared `volatile`.

Example

The following example shows how to declare a public field variable as `volatile`.

```
class VolatileTest
{
    public volatile int sharedStorage;

    public void Test(int i)
    {
        sharedStorage = i;
    }
}
```

The following example demonstrates how an auxiliary or worker thread can be created and used to perform processing in parallel with that of the primary thread. For more information about multithreading, see [Managed Threading](#).

```

public class Worker
{
    // This method is called when the thread is started.
    public void DoWork()
    {
        bool work = false;
        while (!_shouldStop)
        {
            work = !work; // simulate some work
        }
        Console.WriteLine("Worker thread: terminating gracefully.");
    }
    public void RequestStop()
    {
        _shouldStop = true;
    }
    // Keyword volatile is used as a hint to the compiler that this data
    // member is accessed by multiple threads.
    private volatile bool _shouldStop;
}

public class WorkerThreadExample
{
    public static void Main()
    {
        // Create the worker thread object. This does not start the thread.
        Worker workerObject = new Worker();
        Thread workerThread = new Thread(workerObject.DoWork);

        // Start the worker thread.
        workerThread.Start();
        Console.WriteLine("Main thread: starting worker thread...");

        // Loop until the worker thread activates.
        while (!workerThread.IsAlive)
            ;

        // Put the main thread to sleep for 500 milliseconds to
        // allow the worker thread to do some work.
        Thread.Sleep(500);

        // Request that the worker thread stop itself.
        workerObject.RequestStop();

        // Use the Thread.Join method to block the current thread
        // until the object's thread terminates.
        workerThread.Join();
        Console.WriteLine("Main thread: worker thread has terminated.");
    }
    // Sample output:
    // Main thread: starting worker thread...
    // Worker thread: terminating gracefully.
    // Main thread: worker thread has terminated.
}

```

With the `volatile` modifier added to the declaration of `_shouldStop` in place, you'll always get the same results (similar to the excerpt shown in the preceding code). However, without that modifier on the `_shouldStop` member, the behavior is unpredictable. The `DoWork` method may optimize the member access, resulting in reading stale data. Because of the nature of multi-threaded programming, the number of stale reads is unpredictable. Different runs of the program will produce somewhat different results.

C# language specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for

C# syntax and usage.

Statement keywords (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Statements are program instructions. Except as described in the topics referenced in the following table, statements are executed in sequence. The following table lists the C# statement keywords. For more information about statements that are not expressed with any keyword, see [Statements](#).

CATEGORY	C# KEYWORDS
Selection statements	<code>if</code> , <code>switch</code>
Iteration statements	<code>do</code> , <code>for</code> , <code>foreach</code> , <code>while</code>
Jump statements	<code>break</code> , <code>continue</code> , <code>goto</code> , <code>return</code>
Exception handling statements	throw , try-catch , try-finally , try-catch-finally
Checked and unchecked	checked , unchecked
fixed statement	fixed
lock statement	<code>lock</code>
yield statement	<code>yield</code>

throw (C# Reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

Signals the occurrence of an exception during program execution.

Remarks

The syntax of `throw` is:

```
throw [e];
```

where `e` is an instance of a class derived from [System.Exception](#). The following example uses the `throw` statement to throw an [IndexOutOfRangeException](#) if the argument passed to a method named `GetNumber` does not correspond to a valid index of an internal array.

```
using System;

namespace Throw2
{
    public class NumberGenerator
    {
        int[] numbers = { 2, 4, 6, 8, 10, 12, 14, 16, 18, 20 };

        public int GetNumber(int index)
        {
            if (index < 0 || index >= numbers.Length)
            {
                throw new IndexOutOfRangeException();
            }
            return numbers[index];
        }
    }
}
```

Method callers then use a `try-catch` or `try-catch-finally` block to handle the thrown exception. The following example handles the exception thrown by the `GetNumber` method.

```
using System;

public class Example
{
    public static void Main()
    {
        var gen = new NumberGenerator();
        int index = 10;
        try
        {
            int value = gen.GetNumber(index);
            Console.WriteLine($"Retrieved {value}");
        }
        catch (IndexOutOfRangeException e)
        {
            Console.WriteLine($"{e.GetType().Name}: {index} is outside the bounds of the array");
        }
    }
}

// The example displays the following output:
//      IndexOutOfRangeException: 10 is outside the bounds of the array
```

Re-throwing an exception

`throw` can also be used in a `catch` block to re-throw an exception handled in a `catch` block. In this case, `throw` does not take an exception operand. It is most useful when a method passes on an argument from a caller to some other library method, and the library method throws an exception that must be passed on to the caller. For example, the following example re-throws an [NullReferenceException](#) that is thrown when attempting to retrieve the first character of an uninitialized string.

```

using System;

namespace Throw
{
    public class Sentence
    {
        public Sentence(string s)
        {
            Value = s;
        }

        public string Value { get; set; }

        public char GetFirstCharacter()
        {
            try
            {
                return Value[0];
            }
            catch (NullReferenceException e)
            {
                throw;
            }
        }
    }

    public class Example
    {
        public static void Main()
        {
            var s = new Sentence(null);
            Console.WriteLine($"The first character is {s.GetFirstCharacter()}");
        }
    }
}
// The example displays the following output:
//      Unhandled Exception: System.NullReferenceException: Object reference not set to an instance of an
//      object.
//          at Sentence.GetFirstCharacter()
//          at Example.Main()

```

IMPORTANT

You can also use the `throw e` syntax in a `catch` block to instantiate a new exception that you pass on to the caller. In this case, the stack trace of the original exception, which is available from the [StackTrace](#) property, is not preserved.

The `throw` expression

Starting with C# 7.0, `throw` can be used as an expression as well as a statement. This allows an exception to be thrown in contexts that were previously unsupported. These include:

- [the conditional operator](#). The following example uses a `throw` expression to throw an [ArgumentException](#) if a method is passed an empty string array. Before C# 7.0, this logic would need to appear in an `if / else` statement.

```
private static void DisplayFirstNumber(string[] args)
{
    string arg = args.Length >= 1 ? args[0] :
        throw new ArgumentException("You must supply an argument");
    if (Int64.TryParse(arg, out var number))
        Console.WriteLine($"You entered {number:F0}");
    else
        Console.WriteLine($"{arg} is not a number.");
}
```

- [the null-coalescing operator](#). In the following example, a `throw` expression is used with a null-coalescing operator to throw an exception if the string assigned to a `Name` property is `null`.

```
public string Name
{
    get => name;
    set => name = value ??
        throw new ArgumentNullException(paramName: nameof(value), message: "Name cannot be null");
}
```

- an expression-bodied [lambda](#) or method. The following example illustrates an expression-bodied method that throws an [InvalidCastException](#) because a conversion to a [DateTime](#) value is not supported.

```
DateTime ToDateTime(IFormatProvider provider) =>
    throw new InvalidCastException("Conversion to a DateTime is not supported.");
```

C# language specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

See also

- [C# Reference](#)
- [C# Programming Guide](#)
- [try-catch](#)
- [C# Keywords](#)
- [How to: Explicitly Throw Exceptions](#)

try-catch (C# Reference)

12/28/2021 • 9 minutes to read • [Edit Online](#)

The try-catch statement consists of a `try` block followed by one or more `catch` clauses, which specify handlers for different exceptions.

When an exception is thrown, the common language runtime (CLR) looks for the `catch` statement that handles this exception. If the currently executing method does not contain such a `catch` block, the CLR looks at the method that called the current method, and so on up the call stack. If no `catch` block is found, then the CLR displays an unhandled exception message to the user and stops execution of the program.

The `try` block contains the guarded code that may cause the exception. The block is executed until an exception is thrown or it is completed successfully. For example, the following attempt to cast a `null` object raises the [NullReferenceException](#) exception:

```
object o2 = null;
try
{
    int i2 = (int)o2;    // Error
}
```

Although the `catch` clause can be used without arguments to catch any type of exception, this usage is not recommended. In general, you should only catch those exceptions that you know how to recover from. Therefore, you should always specify an object argument derived from [System.Exception](#). The exception type should be as specific as possible in order to avoid incorrectly accepting exceptions that your exception handler is actually not able to resolve. As such, prefer concrete exceptions over the base `Exception` type. For example:

```
catch (InvalidCastException e)
{
    // recover from exception
}
```

It is possible to use more than one specific `catch` clause in the same try-catch statement. In this case, the order of the `catch` clauses is important because the `catch` clauses are examined in order. Catch the more specific exceptions before the less specific ones. The compiler produces an error if you order your catch blocks so that a later block can never be reached.

Using `catch` arguments is one way to filter for the exceptions you want to handle. You can also use an exception filter that further examines the exception to decide whether to handle it. If the exception filter returns false, then the search for a handler continues.

```
catch (ArgumentException e) when (e.ParamName == "...")
{
    // recover from exception
}
```

Exception filters are preferable to catching and rethrowing (explained below) because filters leave the stack unharmed. If a later handler dumps the stack, you can see where the exception originally came from, rather than just the last place it was rethrown. A common use of exception filter expressions is logging. You can create a filter that always returns false that also outputs to a log, you can log exceptions as they go by without having to

handle them and rethrow.

A `throw` statement can be used in a `catch` block to re-throw the exception that is caught by the `catch` statement. The following example extracts source information from an `IOException` exception, and then throws the exception to the parent method.

```
catch (FileNotFoundException e)
{
    // FileNotFoundExceptions are handled here.
}
catch (IOException e)
{
    // Extract some information from this exception, and then
    // throw it to the parent method.
    if (e.Source != null)
        Console.WriteLine("IOException source: {0}", e.Source);
    throw;
}
```

You can catch one exception and throw a different exception. When you do this, specify the exception that you caught as the inner exception, as shown in the following example.

```
catch (InvalidCastException e)
{
    // Perform some action here, and then throw a new exception.
    throw new YourCustomException("Put your error message here.", e);
}
```

You can also re-throw an exception when a specified condition is true, as shown in the following example.

```
catch (InvalidCastException e)
{
    if (e.Data == null)
    {
        throw;
    }
    else
    {
        // Take some action.
    }
}
```

NOTE

It is also possible to use an exception filter to get a similar result in an often cleaner fashion (as well as not modifying the stack, as explained earlier in this document). The following example has a similar behavior for callers as the previous example. The function throws the `InvalidCastException` back to the caller when `e.Data` is `null`.

```
catch (InvalidCastException e) when (e.Data != null)
{
    // Take some action.
}
```

From inside a `try` block, initialize only variables that are declared therein. Otherwise, an exception can occur before the execution of the block is completed. For example, in the following code example, the variable `n` is initialized inside the `try` block. An attempt to use this variable outside the `try` block in the `Write(n)` statement will generate a compiler error.

```
static void Main()
{
    int n;
    try
    {
        // Do not initialize this variable here.
        n = 123;
    }
    catch
    {
    }
    // Error: Use of unassigned local variable 'n'.
    Console.Write(n);
}
```

For more information about catch, see [try-catch-finally](#).

Exceptions in async methods

An async method is marked by an [async](#) modifier and usually contains one or more await expressions or statements. An await expression applies the [await](#) operator to a [Task](#) or [Task<TResult>](#).

When control reaches an `await` in the async method, progress in the method is suspended until the awaited task completes. When the task is complete, execution can resume in the method. For more information, see [Asynchronous programming with async and await](#).

The completed task to which `await` is applied might be in a faulted state because of an unhandled exception in the method that returns the task. Awaiting the task throws an exception. A task can also end up in a canceled state if the asynchronous process that returns it is canceled. Awaiting a canceled task throws an `OperationCanceledException`.

To catch the exception, await the task in a `try` block, and catch the exception in the associated `catch` block. For an example, see the [Async method example](#) section.

A task can be in a faulted state because multiple exceptions occurred in the awaited async method. For example, the task might be the result of a call to [Task.WhenAll](#). When you await such a task, only one of the exceptions is caught, and you can't predict which exception will be caught. For an example, see the [Task.WhenAll example](#) section.

Example

In the following example, the `try` block contains a call to the `ProcessString` method that may cause an exception. The `catch` clause contains the exception handler that just displays a message on the screen. When the `throw` statement is called from inside `ProcessString`, the system looks for the `catch` statement and displays the message `Exception caught`.

```

class TryFinallyTest
{
    static void ProcessString(string s)
    {
        if (s == null)
        {
            throw new ArgumentNullException(paramName: nameof(s), message: "parameter can't be null.");
        }
    }

    public static void Main()
    {
        string s = null; // For demonstration purposes.

        try
        {
            ProcessString(s);
        }
        catch (Exception e)
        {
            Console.WriteLine("{0} Exception caught.", e);
        }
    }
}
/*
Output:
System.ArgumentNullException: Value cannot be null.
   at TryFinallyTest.Main() Exception caught.
* */

```

Two catch blocks example

In the following example, two catch blocks are used, and the most specific exception, which comes first, is caught.

To catch the least specific exception, you can replace the throw statement in `ProcessString` with the following statement: `throw new Exception()`.

If you place the least-specific catch block first in the example, the following error message appears:

```
A previous catch clause already catches all exceptions of this or a super type ('System.Exception').
```

```

class ThrowTest3
{
    static void ProcessString(string s)
    {
        if (s == null)
        {
            throw new ArgumentNullException(paramName: nameof(s), message: "Parameter can't be null");
        }
    }

    public static void Main()
    {
        try
        {
            string s = null;
            ProcessString(s);
        }
        // Most specific:
        catch (ArgumentNullException e)
        {
            Console.WriteLine("{0} First exception caught.", e);
        }
        // Least specific:
        catch (Exception e)
        {
            Console.WriteLine("{0} Second exception caught.", e);
        }
    }
}
/*
Output:
System.ArgumentNullException: Value cannot be null.
at Test.ThrowTest3.ProcessString(String s) ... First exception caught.
*/

```

Async method example

The following example illustrates exception handling for async methods. To catch an exception that an async task throws, place the `await` expression in a `try` block, and catch the exception in a `catch` block.

Uncomment the `throw new Exception` line in the example to demonstrate exception handling. The task's `IsFaulted` property is set to `True`, the task's `Exception.InnerException` property is set to the exception, and the exception is caught in the `catch` block.

Uncomment the `throw new OperationCanceledException` line to demonstrate what happens when you cancel an asynchronous process. The task's `IsCanceled` property is set to `true`, and the exception is caught in the `catch` block. Under some conditions that don't apply to this example, the task's `IsFaulted` property is set to `true` and `IsCanceled` is set to `false`.

```

public async Task DoSomethingAsync()
{
    Task<string> theTask = DelayAsync();

    try
    {
        string result = await theTask;
        Debug.WriteLine("Result: " + result);
    }
    catch (Exception ex)
    {
        Debug.WriteLine("Exception Message: " + ex.Message);
    }
    Debug.WriteLine("Task IsCanceled: " + theTask.IsCanceled);
    Debug.WriteLine("Task IsFaulted: " + theTask.IsFaulted);
    if (theTask.Exception != null)
    {
        Debug.WriteLine("Task Exception Message: "
            + theTask.Exception.Message);
        Debug.WriteLine("Task Inner Exception Message: "
            + theTask.Exception.InnerException.Message);
    }
}

private async Task<string> DelayAsync()
{
    await Task.Delay(100);

    // Uncomment each of the following lines to
    // demonstrate exception handling.

    //throw new OperationCanceledException("canceled");
    //throw new Exception("Something happened.");
    return "Done";
}

// Output when no exception is thrown in the awaited method:
// Result: Done
// Task IsCanceled: False
// Task IsFaulted: False

// Output when an Exception is thrown in the awaited method:
// Exception Message: Something happened.
// Task IsCanceled: False
// Task IsFaulted: True
// Task Exception Message: One or more errors occurred.
// Task Inner Exception Message: Something happened.

// Output when a OperationCanceledException or TaskCanceledException
// is thrown in the awaited method:
// Exception Message: canceled
// Task IsCanceled: True
// Task IsFaulted: False

```

Task.WhenAll example

The following example illustrates exception handling where multiple tasks can result in multiple exceptions. The `try` block awaits the task that's returned by a call to [Task.WhenAll](#). The task is complete when the three tasks to which `WhenAll` is applied are complete.

Each of the three tasks causes an exception. The `catch` block iterates through the exceptions, which are found in the `Exception.InnerExceptions` property of the task that was returned by [Task.WhenAll](#).

```

public async Task DoMultipleAsync()
{
    Task theTask1 = ExcAsync(info: "First Task");
    Task theTask2 = ExcAsync(info: "Second Task");
    Task theTask3 = ExcAsync(info: "Third Task");

    Task allTasks = Task.WhenAll(theTask1, theTask2, theTask3);

    try
    {
        await allTasks;
    }
    catch (Exception ex)
    {
        Debug.WriteLine("Exception: " + ex.Message);
        Debug.WriteLine("Task IsFaulted: " + allTasks.IsFaulted);
        foreach (var inEx in allTasks.Exception.InnerExceptions)
        {
            Debug.WriteLine("Task Inner Exception: " + inEx.Message);
        }
    }
}

private async Task ExcAsync(string info)
{
    await Task.Delay(100);

    throw new Exception("Error-" + info);
}

// Output:
// Exception: Error-First Task
// Task IsFaulted: True
// Task Inner Exception: Error-First Task
// Task Inner Exception: Error-Second Task
// Task Inner Exception: Error-Third Task

```

C# language specification

For more information, see [The try statement](#) section of the [C# language specification](#).

See also

- [C# Reference](#)
- [C# Programming Guide](#)
- [C# Keywords](#)
- [try, throw, and catch Statements \(C++\)](#)
- [throw](#)
- [try-finally](#)
- [How to: Explicitly Throw Exceptions](#)

try-finally (C# Reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

By using a `finally` block, you can clean up any resources that are allocated in a `try` block, and you can run code even if an exception occurs in the `try` block. Typically, the statements of a `finally` block run when control leaves a `try` statement. The transfer of control can occur as a result of normal execution, of execution of a `break`, `continue`, `goto`, or `return` statement, or of propagation of an exception out of the `try` statement.

Within a handled exception, the associated `finally` block is guaranteed to be run. However, if the exception is unhandled, execution of the `finally` block is dependent on how the exception unwind operation is triggered. That, in turn, is dependent on how your computer is set up. The only cases where `finally` clauses don't run involve a program being immediately stopped. An example of this would be when `InvalidProgramException` gets thrown because of the IL statements being corrupt. On most operating systems, reasonable resource cleanup will take place as part of stopping and unloading the process.

Usually, when an unhandled exception ends an application, whether or not the `finally` block is run is not important. However, if you have statements in a `finally` block that must be run even in that situation, one solution is to add a `catch` block to the `try` - `finally` statement. Alternatively, you can catch the exception that might be thrown in the `try` block of a `try` - `finally` statement higher up the call stack. That is, you can catch the exception in the method that calls the method that contains the `try` - `finally` statement, or in the method that calls that method, or in any method in the call stack. If the exception is not caught, execution of the `finally` block depends on whether the operating system chooses to trigger an exception unwind operation.

Example

In the following example, an invalid conversion statement causes a `System.InvalidCastException` exception. The exception is unhandled.

```

public class ThrowTestA
{
    public static void Main()
    {
        int i = 123;
        string s = "Some string";
        object obj = s;

        try
        {
            // Invalid conversion; obj contains a string, not a numeric type.
            i = (int)obj;

            // The following statement is not run.
            Console.WriteLine("WriteLine at the end of the try block.");
        }
        finally
        {
            // To run the program in Visual Studio, type CTRL+F5. Then
            // click Cancel in the error dialog.
            Console.WriteLine("\nExecution of the finally block after an unhandled\n" +
                "error depends on how the exception unwind operation is triggered.");
            Console.WriteLine("i = {0}", i);
        }
    }
}
// Output:
// Unhandled Exception: System.InvalidCastException: Specified cast is not valid.
//
// Execution of the finally block after an unhandled
// error depends on how the exception unwind operation is triggered.
// i = 123
}

```

In the following example, an exception from the `TryCast` method is caught in a method farther up the call stack.

```

public class ThrowTestB
{
    public static void Main()
    {
        try
        {
            // TryCast produces an unhandled exception.
            TryCast();
        }
        catch (Exception ex)
        {
            // Catch the exception that is unhandled in TryCast.
            Console.WriteLine
                ("Catching the {0} exception triggers the finally block.",
                 ex.GetType());

            // Restore the original unhandled exception. You might not
            // know what exception to expect, or how to handle it, so pass
            // it on.
            throw;
        }
    }

    static void TryCast()
    {
        int i = 123;
        string s = "Some string";
        object obj = s;

        try
        {
            // Invalid conversion; obj contains a string, not a numeric type.
            i = (int)obj;

            // The following statement is not run.
            Console.WriteLine("WriteLine at the end of the try block.");
        }
        finally
        {
            // Report that the finally block is run, and show that the value of
            // i has not been changed.
            Console.WriteLine("\nIn the finally block in TryCast, i = {0}.\n", i);
        }
    }
}
// Output:
// In the finally block in TryCast, i = 123.

// Catching the System.InvalidCastException exception triggers the finally block.

// Unhandled Exception: System.InvalidCastException: Specified cast is not valid.
}

```

For more information about `finally`, see [try-catch-finally](#).

C# also contains the [using statement](#), which provides similar functionality for [IDisposable](#) objects in a convenient syntax.

C# language specification

- [How to: Explicitly Throw Exceptions](#)

try-catch-finally (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

A common usage of `catch` and `finally` together is to obtain and use resources in a `try` block, deal with exceptional circumstances in a `catch` block, and release the resources in the `finally` block.

For more information and examples on re-throwing exceptions, see [try-catch](#) and [Throwing Exceptions](#). For more information about the `finally` block, see [try-finally](#).

Example

```
public class EHClass
{
    void ReadFile(int index)
    {
        // To run this code, substitute a valid path from your local machine
        string path = @"c:\users\public\test.txt";
        System.IO.StreamReader file = new System.IO.StreamReader(path);
        char[] buffer = new char[10];
        try
        {
            file.ReadBlock(buffer, index, buffer.Length);
        }
        catch (System.IO.IOException e)
        {
            Console.WriteLine("Error reading from {0}. Message = {1}", path, e.Message);
        }
        finally
        {
            if (file != null)
            {
                file.Close();
            }
        }
        // Do something with buffer...
    }
}
```

Checked and Unchecked (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

C# statements can execute in either checked or unchecked context. In a checked context, arithmetic overflow raises an exception. In an unchecked context, arithmetic overflow is ignored and the result is truncated by discarding any high-order bits that don't fit in the destination type.

- [checked](#) Specify checked context.
- [unchecked](#) Specify unchecked context.

The following operations are affected by the overflow checking:

- Expressions using the following predefined operators on integral types:

`++`, `--`, unary `-`, `+`, `-`, `*`, `/`

- Explicit numeric conversions between integral types, or from `float` or `double` to an integral type.

If neither `checked` nor `unchecked` is specified, the default context for non-constant expressions (expressions that are evaluated at run time) is defined by the value of the [CheckForOverflowUnderflow](#) compiler option. By default the value of that option is unset and arithmetic operations are executed in an unchecked context.

For constant expressions (expressions that can be fully evaluated at compile time), the default context is always checked. Unless a constant expression is explicitly placed in an unchecked context, overflows that occur during the compile-time evaluation of the expression cause compile-time errors.

checked (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `checked` keyword is used to explicitly enable overflow checking for integral-type arithmetic operations and conversions.

By default, an expression that contains only constant values causes a compiler error if the expression produces a value that is outside the range of the destination type. If the expression contains one or more non-constant values, the compiler does not detect the overflow. Evaluating the expression assigned to `i2` in the following example does not cause a compiler error.

```
// The following example causes compiler error CS0220 because 2147483647
// is the maximum value for integers.
//int i1 = 2147483647 + 10;

// The following example, which includes variable ten, does not cause
// a compiler error.
int ten = 10;
int i2 = 2147483647 + ten;

// By default, the overflow in the previous statement also does
// not cause a run-time exception. The following line displays
// -2,147,483,639 as the sum of 2,147,483,647 and 10.
Console.WriteLine(i2);
```

By default, these non-constant expressions are not checked for overflow at run time either, and they do not raise overflow exceptions. The previous example displays -2,147,483,639 as the sum of two positive integers.

Overflow checking can be enabled by compiler options, environment configuration, or use of the `checked` keyword. The following examples demonstrate how to use a `checked` expression or a `checked` block to detect the overflow that is produced by the previous sum at run time. Both examples raise an overflow exception.

```
// If the previous sum is attempted in a checked environment, an
// OverflowException error is raised.

// Checked expression.
Console.WriteLine(checked(2147483647 + ten));

// Checked block.
checked
{
    int i3 = 2147483647 + ten;
    Console.WriteLine(i3);
}
```

The `unchecked` keyword can be used to prevent overflow checking.

Example

This sample shows how to use `checked` to enable overflow checking at run time.

```

class OverFlowTest
{
    // Set maxIntValue to the maximum value for integers.
    static int maxIntValue = 2147483647;

    // Using a checked expression.
    static int CheckedMethod()
    {
        int z = 0;
        try
        {
            // The following line raises an exception because it is checked.
            z = checked(maxIntValue + 10);
        }
        catch (System.OverflowException e)
        {
            // The following line displays information about the error.
            Console.WriteLine("CHECKED and CAUGHT: " + e.ToString());
        }
        // The value of z is still 0.
        return z;
    }

    // Using an unchecked expression.
    static int UncheckedMethod()
    {
        int z = 0;
        try
        {
            // The following calculation is unchecked and will not
            // raise an exception.
            z = maxIntValue + 10;
        }
        catch (System.OverflowException e)
        {
            // The following line will not be executed.
            Console.WriteLine("UNCHECKED and CAUGHT: " + e.ToString());
        }
        // Because of the undetected overflow, the sum of 2147483647 + 10 is
        // returned as -2147483639.
        return z;
    }

    static void Main()
    {
        Console.WriteLine("\nCHECKED output value is: {0}",
            CheckedMethod());
        Console.WriteLine("UNCHECKED output value is: {0}",
            UncheckedMethod());
    }
}
/*
Output:
CHECKED and CAUGHT: System.OverflowException: Arithmetic operation resulted
in an overflow.
    at ConsoleApplication1.OverFlowTest.CheckedMethod()

CHECKED output value is: 0
UNCHECKED output value is: -2147483639
*/
}

```

- [unchecked](#)

unchecked (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `unchecked` keyword is used to suppress overflow-checking for integral-type arithmetic operations and conversions.

In an unchecked context, if an expression produces a value that is outside the range of the destination type, the overflow is not flagged. For example, because the calculation in the following example is performed in an `unchecked` block or expression, the fact that the result is too large for an integer is ignored, and `int1` is assigned the value -2,147,483,639.

```
unchecked
{
    int1 = 2147483647 + 10;
}
int1 = unchecked(ConstantMax + 10);
```

If the `unchecked` environment is removed, a compilation error occurs. The overflow can be detected at compile time because all the terms of the expression are constants.

Expressions that contain non-constant terms are unchecked by default at compile time and run time. See [checked](#) for information about enabling a checked environment.

Because checking for overflow takes time, the use of unchecked code in situations where there is no danger of overflow might improve performance. However, if overflow is a possibility, a checked environment should be used.

Example

This sample shows how to use the `unchecked` keyword.

```

class UncheckedDemo
{
    static void Main(string[] args)
    {
        // int.MaxValue is 2,147,483,647.
        const int ConstantMax = int.MaxValue;
        int int1;
        int int2;
        int variableMax = 2147483647;

        // The following statements are checked by default at compile time. They do not
        // compile.
        //int1 = 2147483647 + 10;
        //int1 = ConstantMax + 10;

        // To enable the assignments to int1 to compile and run, place them inside
        // an unchecked block or expression. The following statements compile and
        // run.
        unchecked
        {
            int1 = 2147483647 + 10;
        }
        int1 = unchecked(ConstantMax + 10);

        // The sum of 2,147,483,647 and 10 is displayed as -2,147,483,639.
        Console.WriteLine(int1);

        // The following statement is unchecked by default at compile time and run
        // time because the expression contains the variable variableMax. It causes
        // overflow but the overflow is not detected. The statement compiles and runs.
        int2 = variableMax + 10;

        // Again, the sum of 2,147,483,647 and 10 is displayed as -2,147,483,639.
        Console.WriteLine(int2);

        // To catch the overflow in the assignment to int2 at run time, put the
        // declaration in a checked block or expression. The following
        // statements compile but raise an overflow exception at run time.
        checked
        {
            //int2 = variableMax + 10;
        }
        //int2 = checked(variableMax + 10);

        // Unchecked sections frequently are used to break out of a checked
        // environment in order to improve performance in a portion of code
        // that is not expected to raise overflow exceptions.
        checked
        {
            // Code that might cause overflow should be executed in a checked
            // environment.
            unchecked
            {
                // This section is appropriate for code that you are confident
                // will not result in overflow, and for which performance is
                // a priority.
            }
            // Additional checked code here.
        }
    }
}

```

fixed Statement (C# Reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

The `fixed` statement prevents the garbage collector from relocating a movable variable. The `fixed` statement is only permitted in an `unsafe` context. You can also use the `fixed` keyword to create [fixed size buffers](#).

The `fixed` statement sets a pointer to a managed variable and "pins" that variable during the execution of the statement. Pointers to movable managed variables are useful only in a `fixed` context. Without a `fixed` context, garbage collection could relocate the variables unpredictably. The C# compiler only lets you assign a pointer to a managed variable in a `fixed` statement.

```
class Point
{
    public int x;
    public int y;
}

unsafe private static void ModifyFixedStorage()
{
    // Variable pt is a managed variable, subject to garbage collection.
    Point pt = new Point();

    // Using fixed allows the address of pt members to be taken,
    // and "pins" pt so that it is not relocated.

    fixed (int* p = &pt.x)
    {
        *p = 1;
    }
}
```

You can initialize a pointer by using an array, a string, a fixed-size buffer, or the address of a variable. The following example illustrates the use of variable addresses, arrays, and strings:

```
Point point = new Point();
double[] arr = { 0, 1.5, 2.3, 3.4, 4.0, 5.9 };
string str = "Hello World";

// The following two assignments are equivalent. Each assigns the address
// of the first element in array arr to pointer p.

// You can initialize a pointer by using an array.
fixed (double* p = arr) { /*...*/ }

// You can initialize a pointer by using the address of a variable.
fixed (double* p = &arr[0]) { /*...*/ }

// The following assignment initializes p by using a string.
fixed (char* p = str) { /*...*/ }

// The following assignment is not valid, because str[0] is a char,
// which is a value, not a variable.
//fixed (char* p = &str[0]) { /*...*/ }
```

Starting with C# 7.3, the `fixed` statement operates on additional types beyond arrays, strings, fixed size buffers, or unmanaged variables. Any type that implements a method named `GetPinnableReference` can be pinned. The

`GetPinnableReference` must return a `ref` variable of an [unmanaged type](#). The .NET types [System.Span<T>](#) and [System.ReadOnlySpan<T>](#) introduced in .NET Core 2.0 make use of this pattern and can be pinned. This is shown in the following example:

```
unsafe private static void FixedSpanExample()
{
    int[] PascalsTriangle = {
        1,
        1, 1,
        1, 2, 1,
        1, 3, 3, 1,
        1, 4, 6, 4, 1,
        1, 5, 10, 10, 5, 1
    };

    Span<int> RowFive = new Span<int>(PascalsTriangle, 10, 5);

    fixed (int* ptrToRow = RowFive)
    {
        // Sum the numbers 1,4,6,4,1
        var sum = 0;
        for (int i = 0; i < RowFive.Length; i++)
        {
            sum += *(ptrToRow + i);
        }
        Console.WriteLine(sum);
    }
}
```

If you are creating types that should participate in this pattern, see [Span<T>.GetPinnableReference\(\)](#) for an example of implementing the pattern.

Multiple pointers can be initialized in one statement if they are all the same type:

```
fixed (byte* ps = srcarray, pd = dstarray) {...}
```

To initialize pointers of different types, simply nest `fixed` statements, as shown in the following example.

```
fixed (int* p1 = &point.x)
{
    fixed (double* p2 = &arr[5])
    {
        // Do something with p1 and p2.
    }
}
```

After the code in the statement is executed, any pinned variables are unpinned and subject to garbage collection. Therefore, do not point to those variables outside the `fixed` statement. The variables declared in the `fixed` statement are scoped to that statement, making this easier:

```
fixed (byte* ps = srcarray, pd = dstarray)
{
    ...
}
// ps and pd are no longer in scope here.
```

Pointers initialized in `fixed` statements are readonly variables. If you want to modify the pointer value, you must declare a second pointer variable, and modify that. The variable declared in the `fixed` statement cannot be modified:

```
fixed (byte* ps = srcarray, pd = dstarray)
{
    byte* pSourceCopy = ps;
    pSourceCopy++; // point to the next element.
    ps++; // invalid: cannot modify ps, as it is declared in the fixed statement.
}
```

You can allocate memory on the stack, where it is not subject to garbage collection and therefore does not need to be pinned. To do that, use a `stackalloc` expression.

C# language specification

Method Parameters (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Parameters declared for a method without [in](#), [ref](#) or [out](#), are passed to the called method by value. That value can be changed in the method, but the changed value will not be retained when control passes back to the calling procedure. By using a method parameter keyword, you can change this behavior.

This section describes the keywords you can use when declaring method parameters:

- [params](#) specifies that this parameter may take a variable number of arguments.
- [in](#) specifies that this parameter is passed by reference but is only read by the called method.
- [ref](#) specifies that this parameter is passed by reference and may be read or written by the called method.
- [out](#) specifies that this parameter is passed by reference and is written by the called method.

See also

- [C# Reference](#)
- [C# Programming Guide](#)
- [C# Keywords](#)

params (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

By using the `params` keyword, you can specify a [method parameter](#) that takes a variable number of arguments. The parameter type must be a single-dimensional array.

No additional parameters are permitted after the `params` keyword in a method declaration, and only one `params` keyword is permitted in a method declaration.

If the declared type of the `params` parameter is not a single-dimensional array, compiler error [CS0225](#) occurs.

When you call a method with a `params` parameter, you can pass in:

- A comma-separated list of arguments of the type of the array elements.
- An array of arguments of the specified type.
- No arguments. If you send no arguments, the length of the `params` list is zero.

Example

The following example demonstrates various ways in which arguments can be sent to a `params` parameter.

```

public class MyClass
{
    public static void UseParams(params int[] list)
    {
        for (int i = 0; i < list.Length; i++)
        {
            Console.Write(list[i] + " ");
        }
        Console.WriteLine();
    }

    public static void UseParams2(params object[] list)
    {
        for (int i = 0; i < list.Length; i++)
        {
            Console.Write(list[i] + " ");
        }
        Console.WriteLine();
    }

    static void Main()
    {
        // You can send a comma-separated list of arguments of the
        // specified type.
        UseParams(1, 2, 3, 4);
        UseParams2(1, 'a', "test");

        // A params parameter accepts zero or more arguments.
        // The following calling statement displays only a blank line.
        UseParams2();

        // An array argument can be passed, as long as the array
        // type matches the parameter type of the method being called.
        int[] myIntArray = { 5, 6, 7, 8, 9 };
        UseParams(myIntArray);

        object[] myObjArray = { 2, 'b', "test", "again" };
        UseParams2(myObjArray);

        // The following call causes a compiler error because the object
        // array cannot be converted into an integer array.
        //UseParams(myObjArray);

        // The following call does not cause an error, but the entire
        // integer array becomes the first element of the params array.
        UseParams2(myIntArray);
    }
}
/*
Output:
1 2 3 4
1 a test

5 6 7 8 9
2 b test again
System.Int32[]
*/

```

- [Method Parameters](#)

in parameter modifier (C# Reference)

12/28/2021 • 5 minutes to read • [Edit Online](#)

The `in` keyword causes arguments to be passed by reference but ensures the argument is not modified. It makes the formal parameter an alias for the argument, which must be a variable. In other words, any operation on the parameter is made on the argument. It is like the `ref` or `out` keywords, except that `in` arguments cannot be modified by the called method. Whereas `ref` arguments may be modified, `out` arguments must be modified by the called method, and those modifications are observable in the calling context.

```
int readonlyArgument = 44;
InArgExample(readonlyArgument);
Console.WriteLine(readonlyArgument);    // value is still 44

void InArgExample(in int number)
{
    // Uncomment the following line to see error CS8331
    //number = 19;
}
```

The preceding example demonstrates that the `in` modifier is usually unnecessary at the call site. It is only required in the method declaration.

NOTE

The `in` keyword can also be used with a generic type parameter to specify that the type parameter is contravariant, as part of a `foreach` statement, or as part of a `join` clause in a LINQ query. For more information on the use of the `in` keyword in these contexts, see [in](#), which provides links to all those uses.

Variables passed as `in` arguments must be initialized before being passed in a method call. However, the called method may not assign a value or modify the argument.

The `in` parameter modifier is available in C# 7.2 and later. Previous versions generate compiler error `CS8107` ("Feature 'readonly references' is not available in C# 7.0. Please use language version 7.2 or greater.") To configure the compiler language version, see [Select the C# language version](#).

Although `in`, `out`, and `ref` parameter modifiers are considered part of a signature, members declared in a single type cannot differ in signature solely by `in`, `ref` and `out`. Therefore, methods cannot be overloaded if the only difference is that one method takes a `ref` or `in` argument and the other takes an `out` argument. The following code, for example, will not compile:

```
class CS0663_Example
{
    // Compiler error CS0663: "Cannot define overloaded
    // methods that differ only on in, ref and out".
    public void SampleMethod(in int i) { }
    public void SampleMethod(ref int i) { }
}
```

Overloading based on the presence of `in` is allowed:

```
class InOverloads
{
    public void SampleMethod(in int i) { }
    public void SampleMethod(int i) { }
}
```

Overload resolution rules

You can understand the overload resolution rules for methods with by value vs. `in` arguments by understanding the motivation for `in` arguments. Defining methods using `in` parameters is a potential performance optimization. Some `struct` type arguments may be large in size, and when methods are called in tight loops or critical code paths, the cost of copying those structures is critical. Methods declare `in` parameters to specify that arguments may be passed by reference safely because the called method does not modify the state of that argument. Passing those arguments by reference avoids the (potentially) expensive copy.

Specifying `in` for arguments at the call site is typically optional. There is no semantic difference between passing arguments by value and passing them by reference using the `in` modifier. The `in` modifier at the call site is optional because you don't need to indicate that the argument's value might be changed. You explicitly add the `in` modifier at the call site to ensure the argument is passed by reference, not by value. Explicitly using `in` has the following two effects:

First, specifying `in` at the call site forces the compiler to select a method defined with a matching `in` parameter. Otherwise, when two methods differ only in the presence of `in`, the by value overload is a better match.

Second, specifying `in` declares your intent to pass an argument by reference. The argument used with `in` must represent a location that can be directly referred to. The same general rules for `out` and `ref` arguments apply: You cannot use constants, ordinary properties, or other expressions that produce values. Otherwise, omitting `in` at the call site informs the compiler that you will allow it to create a temporary variable to pass by read-only reference to the method. The compiler creates a temporary variable to overcome several restrictions with `in` arguments:

- A temporary variable allows compile-time constants as `in` parameters.
- A temporary variable allows properties, or other expressions for `in` parameters.
- A temporary variable allows arguments where there is an implicit conversion from the argument type to the parameter type.

In all the preceding instances, the compiler creates a temporary variable that stores the value of the constant, property, or other expression.

The following code illustrates these rules:

```
static void Method(in int argument)
{
    // implementation removed
}

Method(5); // OK, temporary variable created.
Method(5L); // CS1503: no implicit conversion from long to int
short s = 0;
Method(s); // OK, temporary int created with the value 0
Method(in s); // CS1503: cannot convert from in short to in int
int i = 42;
Method(i); // passed by readonly reference
Method(in i); // passed by readonly reference, explicitly using `in`
```

Now, suppose another method using by value arguments was available. The results change as shown in the following code:

```
static void Method(int argument)
{
    // implementation removed
}

static void Method(in int argument)
{
    // implementation removed
}

Method(5); // Calls overload passed by value
Method(5L); // CS1503: no implicit conversion from long to int
short s = 0;
Method(s); // Calls overload passed by value.
Method(in s); // CS1503: cannot convert from in short to in int
int i = 42;
Method(i); // Calls overload passed by value
Method(in i); // passed by readonly reference, explicitly using `in`
```

The only method call where the argument is passed by reference is the final one.

NOTE

The preceding code uses `int` as the argument type for simplicity. Because `int` is no larger than a reference in most modern machines, there is no benefit to passing a single `int` as a readonly reference.

Limitations on `in` parameters

You can't use the `in`, `ref`, and `out` keywords for the following kinds of methods:

- Async methods, which you define by using the `async` modifier.
- Iterator methods, which include a `yield return` or `yield break` statement.
- The first argument of an extension method cannot have the `in` modifier unless that argument is a struct.
- The first argument of an extension method where that argument is a generic type (even when that type is constrained to be a struct.)

You can learn more about the `in` modifier, how it differs from `ref` and `out` in the article on [Write safe efficient code](#).

C# Language Specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

ref (C# Reference)

12/28/2021 • 9 minutes to read • [Edit Online](#)

The `ref` keyword indicates that a value is passed by reference. It is used in four different contexts:

- In a method signature and in a method call, to pass an argument to a method by reference. For more information, see [Passing an argument by reference](#).
- In a method signature, to return a value to the caller by reference. For more information, see [Reference return values](#).
- In a member body, to indicate that a reference return value is stored locally as a reference that the caller intends to modify. Or to indicate that a local variable accesses another value by reference. For more information, see [Ref locals](#).
- In a `struct` declaration, to declare a `ref struct` or a `readonly ref struct`. For more information, see the [ref struct](#) section of the [Structure types](#) article.

Passing an argument by reference

When used in a method's parameter list, the `ref` keyword indicates that an argument is passed by reference, not by value. The `ref` keyword makes the formal parameter an alias for the argument, which must be a variable. In other words, any operation on the parameter is made on the argument.

For example, suppose the caller passes a local variable expression or an array element access expression. The called method can then replace the object to which the `ref` parameter refers. In that case, the caller's local variable or the array element refers to the new object when the method returns.

NOTE

Don't confuse the concept of passing by reference with the concept of reference types. The two concepts are not the same. A method parameter can be modified by `ref` regardless of whether it is a value type or a reference type. There is no boxing of a value type when it is passed by reference.

To use a `ref` parameter, both the method definition and the calling method must explicitly use the `ref` keyword, as shown in the following example. (Except that the calling method can omit `ref` when making a COM call.)

```
void Method(ref int refArgument)
{
    refArgument = refArgument + 44;
}

int number = 1;
Method(ref number);
Console.WriteLine(number);
// Output: 45
```

An argument that is passed to a `ref` or `in` parameter must be initialized before it is passed. This requirement differs from `out` parameters, whose arguments don't have to be explicitly initialized before they are passed.

Members of a class can't have signatures that differ only by `ref`, `in`, or `out`. A compiler error occurs if the only difference between two members of a type is that one of them has a `ref` parameter and the other has an `out`, or `in` parameter. The following code, for example, doesn't compile.

```
class CS0663_Example
{
    // Compiler error CS0663: "Cannot define overloaded
    // methods that differ only on ref and out".
    public void SampleMethod(out int i) { }
    public void SampleMethod(ref int i) { }
}
```

However, methods can be overloaded when one method has a `ref`, `in`, or `out` parameter and the other has a parameter that is passed by value, as shown in the following example.

```
class RefOverloadExample
{
    public void SampleMethod(int i) { }
    public void SampleMethod(ref int i) { }
}
```

In other situations that require signature matching, such as hiding or overriding, `in`, `ref`, and `out` are part of the signature and don't match each other.

Properties are not variables. They're methods, and cannot be passed to `ref` parameters.

You can't use the `ref`, `in`, and `out` keywords for the following kinds of methods:

- Async methods, which you define by using the [async](#) modifier.
- Iterator methods, which include a [yield return](#) or `yield break` statement.

[extension methods](#) also have restrictions on the use of these keywords:

- The `out` keyword cannot be used on the first argument of an extension method.
- The `ref` keyword cannot be used on the first argument of an extension method when the argument is not a struct, or a generic type not constrained to be a struct.
- The `in` keyword cannot be used unless the first argument is a struct. The `in` keyword cannot be used on any generic type, even when constrained to be a struct.

Passing an argument by reference: An example

The previous examples pass value types by reference. You can also use the `ref` keyword to pass reference types by reference. Passing a reference type by reference enables the called method to replace the object to which the reference parameter refers in the caller. The storage location of the object is passed to the method as the value of the reference parameter. If you change the value in the storage location of the parameter (to point to a new object), you also change the storage location to which the caller refers. The following example passes an instance of a reference type as a `ref` parameter.

```

class Product
{
    public Product(string name, int newID)
    {
        ItemName = name;
        ItemID = newID;
    }

    public string ItemName { get; set; }
    public int ItemID { get; set; }
}

private static void ChangeByReference(ref Product itemRef)
{
    // Change the address that is stored in the itemRef parameter.
    itemRef = new Product("Stapler", 99999);

    // You can change the value of one of the properties of
    // itemRef. The change happens to item in Main as well.
    itemRef.ItemID = 12345;
}

private static void ModifyProductsByReference()
{
    // Declare an instance of Product and display its initial values.
    Product item = new Product("Fasteners", 54321);
    System.Console.WriteLine("Original values in Main. Name: {0}, ID: {1}\n",
        item.ItemName, item.ItemID);

    // Pass the product instance to ChangeByReference.
    ChangeByReference(ref item);
    System.Console.WriteLine("Back in Main. Name: {0}, ID: {1}\n",
        item.ItemName, item.ItemID);
}

// This method displays the following output:
// Original values in Main. Name: Fasteners, ID: 54321
// Back in Main. Name: Stapler, ID: 12345

```

For more information about how to pass reference types by value and by reference, see [Passing Reference-Type Parameters](#).

Reference return values

Reference return values (or `ref` returns) are values that a method returns by reference to the caller. That is, the caller can modify the value returned by a method, and that change is reflected in the state of the object in the calling method.

A reference return value is defined by using the `ref` keyword:

- In the method signature. For example, the following method signature indicates that the `GetCurrentPrice` method returns a `Decimal` value by reference.

```
public ref decimal GetCurrentPrice()
```

- Between the `return` token and the variable returned in a `return` statement in the method. For example:

```
return ref DecimalArray[0];
```

In order for the caller to modify the object's state, the reference return value must be stored to a variable that is explicitly defined as a [ref local](#).

Here's a more complete ref return example, showing both the method signature and method body.

```
public static ref int Find(int[,] matrix, Func<int, bool> predicate)
{
    for (int i = 0; i < matrix.GetLength(0); i++)
        for (int j = 0; j < matrix.GetLength(1); j++)
            if (predicate(matrix[i, j]))
                return ref matrix[i, j];
    throw new InvalidOperationException("Not found");
}
```

The called method may also declare the return value as `ref readonly` to return the value by reference, and enforce that the calling code can't modify the returned value. The calling method can avoid copying the returned value by storing the value in a local [ref readonly](#) variable.

For an example, see [A ref returns and ref locals example](#).

Ref locals

A ref local variable is used to refer to values returned using `return ref`. A ref local variable cannot be initialized to a non-ref return value. In other words, the right-hand side of the initialization must be a reference. Any modifications to the value of the ref local are reflected in the state of the object whose method returned the value by reference.

You define a ref local by using the `ref` keyword in two places:

- Before the variable declaration.
- Immediately before the call to the method that returns the value by reference.

For example, the following statement defines a ref local value that is returned by a method named `GetEstimatedValue`:

```
ref decimal estValue = ref Building.GetEstimatedValue();
```

You can access a value by reference in the same way. In some cases, accessing a value by reference increases performance by avoiding a potentially expensive copy operation. For example, the following statement shows how to define a ref local variable that is used to reference a value.

```
ref VeryLargeStruct reflocal = ref veryLargeStruct;
```

In both examples the `ref` keyword must be used in both places, or the compiler generates error CS8172, "Cannot initialize a by-reference variable with a value."

Beginning with C# 7.3, the iteration variable of the `foreach` statement can be a ref local or ref readonly local variable. For more information, see the [foreach statement](#) article.

Also beginning with C# 7.3, you can reassign a ref local or ref readonly local variable with the [ref assignment operator](#).

Ref readonly locals

A ref readonly local is used to refer to values returned by a method or property that has `ref readonly` in its

signature and uses `return ref`. A `ref readonly` variable combines the properties of a `ref` local variable with a `readonly` variable: it's an alias to the storage it's assigned to, and it cannot be modified.

A ref returns and ref locals example

The following example defines a `Book` class that has two `String` fields, `Title` and `Author`. It also defines a `BookCollection` class that includes a private array of `Book` objects. Individual book objects are returned by reference by calling its `GetBookByTitle` method.

```
public class Book
{
    public string Author;
    public string Title;
}

public class BookCollection
{
    private Book[] books = { new Book { Title = "Call of the Wild, The", Author = "Jack London" },
                             new Book { Title = "Tale of Two Cities, A", Author = "Charles Dickens" }
    };
    private Book nobook = null;

    public ref Book GetBookByTitle(string title)
    {
        for (int ctr = 0; ctr < books.Length; ctr++)
        {
            if (title == books[ctr].Title)
                return ref books[ctr];
        }
        return ref nobook;
    }

    public void ListBooks()
    {
        foreach (var book in books)
        {
            Console.WriteLine($"{book.Title}, by {book.Author}");
        }
        Console.WriteLine();
    }
}
```

When the caller stores the value returned by the `GetBookByTitle` method as a ref local, changes that the caller makes to the return value are reflected in the `BookCollection` object, as the following example shows.

```
var bc = new BookCollection();
bc.ListBooks();

ref var book = ref bc.GetBookByTitle("Call of the Wild, The");
if (book != null)
    book = new Book { Title = "Republic, The", Author = "Plato" };
bc.ListBooks();
// The example displays the following output:
//      Call of the Wild, The, by Jack London
//      Tale of Two Cities, A, by Charles Dickens
//
//      Republic, The, by Plato
//      Tale of Two Cities, A, by Charles Dickens
```

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

out parameter modifier (C# Reference)

12/28/2021 • 4 minutes to read • [Edit Online](#)

The `out` keyword causes arguments to be passed by reference. It makes the formal parameter an alias for the argument, which must be a variable. In other words, any operation on the parameter is made on the argument. It is like the `ref` keyword, except that `ref` requires that the variable be initialized before it is passed. It is also like the `in` keyword, except that `in` does not allow the called method to modify the argument value. To use an `out` parameter, both the method definition and the calling method must explicitly use the `out` keyword. For example:

```
int initializeInMethod;  
OutArgExample(out initializeInMethod);  
Console.WriteLine(initializeInMethod);    // value is now 44  
  
void OutArgExample(out int number)  
{  
    number = 44;  
}
```

NOTE

The `out` keyword can also be used with a generic type parameter to specify that the type parameter is covariant. For more information on the use of the `out` keyword in this context, see [out \(Generic Modifier\)](#).

Variables passed as `out` arguments do not have to be initialized before being passed in a method call. However, the called method is required to assign a value before the method returns.

The `in`, `ref`, and `out` keywords are not considered part of the method signature for the purpose of overload resolution. Therefore, methods cannot be overloaded if the only difference is that one method takes a `ref` or `in` argument and the other takes an `out` argument. The following code, for example, will not compile:

```
class CS0663_Example  
{  
    // Compiler error CS0663: "Cannot define overloaded  
    // methods that differ only on ref and out".  
    public void SampleMethod(out int i) { }  
    public void SampleMethod(ref int i) { }  
}
```

Overloading is legal, however, if one method takes a `ref`, `in`, or `out` argument and the other has none of those modifiers, like this:

```
class OutOverloadExample  
{  
    public void SampleMethod(int i) { }  
    public void SampleMethod(out int i) => i = 5;  
}
```

The compiler chooses the best overload by matching the parameter modifiers at the call site to the parameter modifiers used in the method call.

Properties are not variables and therefore cannot be passed as `out` parameters.

You can't use the `in`, `ref`, and `out` keywords for the following kinds of methods:

- Async methods, which you define by using the `async` modifier.
- Iterator methods, which include a `yield return` or `yield break` statement.

In addition, `extension methods` have the following restrictions:

- The `out` keyword cannot be used on the first argument of an extension method.
- The `ref` keyword cannot be used on the first argument of an extension method when the argument is not a struct, or a generic type not constrained to be a struct.
- The `in` keyword cannot be used unless the first argument is a struct. The `in` keyword cannot be used on any generic type, even when constrained to be a struct.

Declaring `out` parameters

Declaring a method with `out` arguments is a classic workaround to return multiple values. Beginning with C# 7.0, consider `value tuples` for similar scenarios. The following example uses `out` to return three variables with a single method call. The third argument is assigned to null. This enables methods to return values optionally.

```
void Method(out int answer, out string message, out string stillNull)
{
    answer = 44;
    message = "I've been returned";
    stillNull = null;
}

int argNumber;
string argMessage, argDefault;
Method(out argNumber, out argMessage, out argDefault);
Console.WriteLine(argNumber);
Console.WriteLine(argMessage);
Console.WriteLine(argDefault == null);

// The example displays the following output:
//      44
//      I've been returned
//      True
```

Calling a method with an `out` argument

In C# 6 and earlier, you must declare a variable in a separate statement before you pass it as an `out` argument. The following example declares a variable named `number` before it is passed to the `Int32.TryParse` method, which attempts to convert a string to a number.

```
string numberAsString = "1640";

int number;
if (Int32.TryParse(numberAsString, out number))
    Console.WriteLine($"Converted '{numberAsString}' to {number}");
else
    Console.WriteLine($"Unable to convert '{numberAsString}'");
// The example displays the following output:
//      Converted '1640' to 1640
```

Starting with C# 7.0, you can declare the `out` variable in the argument list of the method call, rather than in a separate variable declaration. This produces more compact, readable code, and also prevents you from inadvertently assigning a value to the variable before the method call. The following example is like the previous example, except that it defines the `number` variable in the call to the [Int32.TryParse](#) method.

```
string numberAsString = "1640";

if (Int32.TryParse(numberAsString, out int number))
    Console.WriteLine($"Converted '{numberAsString}' to {number}");
else
    Console.WriteLine($"Unable to convert '{numberAsString}'");
// The example displays the following output:
//      Converted '1640' to 1640
```

In the previous example, the `number` variable is strongly typed as an `int`. You can also declare an implicitly typed local variable, as the following example does.

```
string numberAsString = "1640";

if (Int32.TryParse(numberAsString, out var number))
    Console.WriteLine($"Converted '{numberAsString}' to {number}");
else
    Console.WriteLine($"Unable to convert '{numberAsString}'");
// The example displays the following output:
//      Converted '1640' to 1640
```

C# Language Specification

- [Method Parameters](#)

namespace

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `namespace` keyword is used to declare a scope that contains a set of related objects. You can use a namespace to organize code elements and to create globally unique types.

```
namespace SampleNamespace
{
    class SampleClass { }

    interface ISampleInterface { }

    struct SampleStruct { }

    enum SampleEnum { a, b }

    delegate void SampleDelegate(int i);

    namespace Nested
    {
        class SampleClass2 { }
    }
}
```

File scoped namespace declarations enable you to declare that all types in a file are in a single namespace. File scoped namespace declarations are available with C# 10. The following example is similar to the previous example, but uses a file scoped namespace declaration:

```
using System;

namespace SampleFileScopedNamespace;

class SampleClass { }

interface ISampleInterface { }

struct SampleStruct { }

enum SampleEnum { a, b }

delegate void SampleDelegate(int i);
```

The preceding example doesn't include a nested namespace. File scoped namespaces can't include additional namespace declarations. You cannot declare a nested namespace or a second file-scoped namespace:

```

namespace SampleNamespace;

class AnotherSampleClass
{
    public void AnotherSampleMethod()
    {
        System.Console.WriteLine(
            "SampleMethod inside SampleNamespace");
    }
}

namespace AnotherNamespace; // Not allowed!

namespace ANestedNamespace // Not allowed!
{
    // declarations...
}

```

Within a namespace, you can declare zero or more of the following types:

- [class](#)
- [interface](#)
- [struct](#)
- [enum](#)
- [delegate](#)
- nested namespaces can be declared except in file scoped namespace declarations

The compiler adds a default namespace. This unnamed namespace, sometimes referred to as the global namespace, is present in every file. It contains declarations not included in a declared namespace. Any identifier in the global namespace is available for use in a named namespace.

Namespaces implicitly have public access. For a discussion of the access modifiers you can assign to elements in a namespace, see [Access Modifiers](#).

It's possible to define a namespace in two or more declarations. For example, the following example defines two classes as part of the `MyCompany` namespace:

```

namespace MyCompany.Proj1
{
    class MyClass
    {
    }
}

namespace MyCompany.Proj1
{
    class MyClass1
    {
    }
}

```

The following example shows how to call a static method in a nested namespace.

```
namespace SomeNameSpace
{
    public class MyClass
    {
        static void Main()
        {
            Nested.NestedNameSpaceClass.SayHello();
        }
    }

    // a nested namespace
    namespace Nested
    {
        public class NestedNameSpaceClass
        {
            public static void SayHello()
            {
                Console.WriteLine("Hello");
            }
        }
    }
}
// Output: Hello
```

C# language specification

For more information, see the [Namespaces](#) section of the [C# language specification](#). For more information on file scoped namespace declarations, see the [feature specification](#).

- [using](#)
- [using static](#)
- [Namespace alias qualifier](#) `::`
- [Namespaces](#)

using (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `using` keyword has two major uses:

- The [using statement](#) defines a scope at the end of which an object will be disposed.
- The [using directive](#) creates an alias for a namespace or imports types defined in other namespaces.

See also

- [C# Reference](#)
- [C# Programming Guide](#)
- [C# Keywords](#)
- [Namespaces](#)
- [extern](#)

using directive

12/28/2021 • 9 minutes to read • [Edit Online](#)

The `using` directive allows you to use types defined in a namespace without specifying the fully qualified namespace of that type. In its basic form, the `using` directive imports all the types from a single namespace, as shown in the following example:

```
using System.Text;
```

You can apply two modifiers to a `using` directive:

- The `global` modifier has the same effect as adding the same `using` directive to every source file in your project. This modifier was introduced in C# 10.
- The `static` modifier imports the `static` members and nested types from a single type rather than importing all the types in a namespace. This modifier was introduced in C# 6.0.

You can combine both modifiers to import the static members from a type in all source files in your project.

You can also create an alias for a namespace or a type with a *using alias directive*.

```
using Project = PC.MyCompany.Project;
```

You can use the `global` modifier on a *using alias directive*.

NOTE

The `using` keyword is also used to create *using statements*, which help ensure that `IDisposable` objects such as files and fonts are handled correctly. For more information about the *using statement*, see [using Statement](#).

The scope of a `using` directive without the `global` modifier is the file in which it appears.

The `using` directive can appear:

- At the beginning of a source code file, before any namespace or type declarations.
- In any namespace, but before any namespaces or types declared in that namespace, unless the `global` modifier is used, in which case the directive must appear before all namespace and type declarations.

Otherwise, compiler error [CS1529](#) is generated.

Create a `using` directive to use the types in a namespace without having to specify the namespace. A `using` directive doesn't give you access to any namespaces that are nested in the namespace you specify. Namespaces come in two categories: user-defined and system-defined. User-defined namespaces are namespaces defined in your code. For a list of the system-defined namespaces, see [.NET API Browser](#).

global modifier

Adding the `global` modifier to a `using` directive means that using is applied to all files in the compilation (typically a project). The `global using` directive was added in C# 10. Its syntax is:

```
global using <fully-qualified-namespace>;
```

where *fully-qualified-namespace* is the fully qualified name of the namespace whose types can be referenced without specifying the namespace.

A *global using* directive can appear at the beginning of any source code file. All `global using` directives in a single file must appear before:

- All `using` directives without the `global` modifier.
- All namespace and type declarations in the file.

You may add `global using` directives to any source file. Typically, you'll want to keep them in a single location. The order of `global using` directives doesn't matter, either in a single file, or between files.

The `global` modifier may be combined with the `static` modifier. The `global` modifier may be applied to a *using alias directive*. In both cases, the directive's scope is all files in the current compilation. The following example enables using all the methods declared in the [System.Math](#) in all files in your project:

```
global using static System.Math;
```

You can also globally include a namespace by adding a `<Using>` item to your project file, for example, `<Using Include="My.Awesome.Namespace" />`. For more information, see [<Using> item](#).

IMPORTANT

The C# templates for .NET 6 use *top level statements*. Your application may not match the code in this article, if you've already upgraded to the .NET 6 previews. For more information see the article on [New C# templates generate top level statements](#)

The .NET 6 SDK also adds a set of *implicit* `global using` directives for projects that use the following SDKs:

- Microsoft.NET.Sdk
- Microsoft.NET.Sdk.Web
- Microsoft.NET.Sdk.Worker

These implicit `global using` directives include the most common namespaces for the project type.

static modifier

The `using static` directive names a type whose static members and nested types you can access without specifying a type name. The `using static` directive was introduced in C# 6. Its syntax is:

```
using static <fully-qualified-type-name>;
```

The `<fully-qualified-type-name>` is the name of the type whose static members and nested types can be referenced without specifying a type name. If you don't provide a fully qualified type name (the full namespace name along with the type name), C# generates compiler error [CS0246](#): "The type or namespace name 'type/namespace' couldn't be found (are you missing a using directive or an assembly reference?)".

The `using static` directive applies to any type that has static members (or nested types), even if it also has instance members. However, instance members can only be invoked through the type instance.

You can access static members of a type without having to qualify the access with the type name:

```
using static System.Console;
using static System.Math;
class Program
{
    static void Main()
    {
        WriteLine(Sqrt(3*3 + 4*4));
    }
}
```

Ordinarily, when you call a static member, you provide the type name along with the member name. Repeatedly entering the same type name to invoke members of the type can result in verbose, obscure code. For example, the following definition of a `Circle` class references many members of the `Math` class.

```
using System;

public class Circle
{
    public Circle(double radius)
    {
        Radius = radius;
    }

    public double Radius { get; set; }

    public double Diameter
    {
        get { return 2 * Radius; }
    }

    public double Circumference
    {
        get { return 2 * Radius * Math.PI; }
    }

    public double Area
    {
        get { return Math.PI * Math.Pow(Radius, 2); }
    }
}
```

By eliminating the need to explicitly reference the `Math` class each time a member is referenced, the `using static` directive produces cleaner code:

```

using System;
using static System.Math;

public class Circle
{
    public Circle(double radius)
    {
        Radius = radius;
    }

    public double Radius { get; set; }

    public double Diameter
    {
        get { return 2 * Radius; }
    }

    public double Circumference
    {
        get { return 2 * Radius * PI; }
    }

    public double Area
    {
        get { return PI * Pow(Radius, 2); }
    }
}

```

`using static` imports only accessible static members and nested types declared in the specified type. Inherited members aren't imported. You can import from any named type with a `using static` directive, including Visual Basic modules. If F# top-level functions appear in metadata as static members of a named type whose name is a valid C# identifier, then the F# functions can be imported.

`using static` makes extension methods declared in the specified type available for extension method lookup. However, the names of the extension methods aren't imported into scope for unqualified reference in code.

Methods with the same name imported from different types by different `using static` directives in the same compilation unit or namespace form a method group. Overload resolution within these method groups follows normal C# rules.

The following example uses the `using static` directive to make the static members of the [Console](#), [Math](#), and [String](#) classes available without having to specify their type name.

```

using System;
using static System.Console;
using static System.Math;
using static System.String;

class Program
{
    static void Main()
    {
        Write("Enter a circle's radius: ");
        var input = ReadLine();
        if (!IsNullOrEmpty(input) && double.TryParse(input, out var radius)) {
            var c = new Circle(radius);

            string s = "\nInformation about the circle:\n";
            s = s + Format("    Radius: {0:N2}\n", c.Radius);
            s = s + Format("    Diameter: {0:N2}\n", c.Diameter);
            s = s + Format("    Circumference: {0:N2}\n", c.Circumference);
            s = s + Format("    Area: {0:N2}\n", c.Area);
            WriteLine(s);
        }
        else {
            WriteLine("Invalid input...");
        }
    }
}

public class Circle
{
    public Circle(double radius)
    {
        Radius = radius;
    }

    public double Radius { get; set; }

    public double Diameter
    {
        get { return 2 * Radius; }
    }

    public double Circumference
    {
        get { return 2 * Radius * PI; }
    }

    public double Area
    {
        get { return PI * Pow(Radius, 2); }
    }
}

// The example displays the following output:
//      Enter a circle's radius: 12.45
//
//      Information about the circle:
//          Radius: 12.45
//          Diameter: 24.90
//          Circumference: 78.23
//          Area: 486.95

```

In the example, the `using static` directive could also have been applied to the `Double` type. Adding that directive would make it possible to call the `TryParse(String, Double)` method without specifying a type name. However, using `TryParse` without a type name creates less readable code, since it becomes necessary to check the `using static` directives to determine which numeric type's `TryParse` method is called.

`using static` also applies to `enum` types. By adding `using static` with the enum, the type is no longer required to use the enum members.

```
using static Color;

enum Color
{
    Red,
    Green,
    Blue
}

class Program
{
    public static void Main()
    {
        Color color = Green;
    }
}
```

using alias

Create a `using` alias directive to make it easier to qualify an identifier to a namespace or type. In any `using` directive, the fully qualified namespace or type must be used regardless of the `using` directives that come before it. No `using` alias can be used in the declaration of a `using` directive. For example, the following example generates a compiler error:

```
using s = System.Text;
using s.RegularExpressions; // Generates a compiler error.
```

The following example shows how to define and use a `using` alias for a namespace:

```
namespace PC
{
    // Define an alias for the nested namespace.
    using Project = PC.MyCompany.Project;
    class A
    {
        void M()
        {
            // Use the alias
            var mc = new Project.MyClass();
        }
    }
    namespace MyCompany
    {
        namespace Project
        {
            public class MyClass { }
        }
    }
}
```

A `using` alias directive can't have an open generic type on the right-hand side. For example, you can't create a `using` alias for a `List<T>`, but you can create one for a `List<int>`.

The following example shows how to define a `using` directive and a `using` alias for a class:

```

using System;

// Using alias directive for a class.
using AliasToMyClass = NameSpace1.MyClass;

// Using alias directive for a generic class.
using UsingAlias = NameSpace2.MyClass<int>;

namespace NameSpace1
{
    public class MyClass
    {
        public override string ToString()
        {
            return "You are in NameSpace1.MyClass.";
        }
    }
}

namespace NameSpace2
{
    class MyClass<T>
    {
        public override string ToString()
        {
            return "You are in NameSpace2.MyClass.";
        }
    }
}

namespace NameSpace3
{
    class MainClass
    {
        static void Main()
        {
            var instance1 = new AliasToMyClass();
            Console.WriteLine(instance1);

            var instance2 = new UsingAlias();
            Console.WriteLine(instance2);
        }
    }
}
// Output:
//   You are in NameSpace1.MyClass.
//   You are in NameSpace2.MyClass.

```

How to use the Visual Basic `My` namespace

The [Microsoft.VisualBasic.MyServices](#) namespace (`My` in Visual Basic) provides easy and intuitive access to a number of .NET classes, enabling you to write code that interacts with the computer, application, settings, resources, and so on. Although originally designed for use with Visual Basic, the `MyServices` namespace can be used in C# applications.

For more information about using the `MyServices` namespace from Visual Basic, see [Development with My](#).

You need to add a reference to the *Microsoft.VisualBasic.dll* assembly in your project. Not all the classes in the `MyServices` namespace can be called from a C# application: for example, the [FileSystemProxy](#) class is not compatible. In this particular case, the static methods that are part of [FileSystem](#), which are also contained in *VisualBasic.dll*, can be used instead. For example, here is how to use one such method to duplicate a directory:

```
// Duplicate a directory
Microsoft.VisualBasic.FileIO.FileSystem.CopyDirectory(
    @"C:\original_directory",
    @"C:\copy_of_original_directory");
```

C# language specification

For more information, see [Using directives](#) in the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

For more information on the *global using* modifier, see the [global usings feature specification - C# 10](#).

using statement (C# Reference)

12/28/2021 • 4 minutes to read • [Edit Online](#)

Provides a convenient syntax that ensures the correct use of [IDisposable](#) objects. Beginning in C# 8.0, the `using` statement ensures the correct use of [IAsyncDisposable](#) objects.

Example

The following example shows how to use the `using` statement.

```
string manyLines = @"This is line one
This is line two
Here is line three
The penultimate line is line four
This is the final, fifth line.";

using (var reader = new StringReader(manyLines))
{
    string? item;
    do
    {
        item = reader.ReadLine();
        Console.WriteLine(item);
    } while (item != null);
}
```

Beginning with C# 8.0, you can use the following alternative syntax for the `using` statement that doesn't require braces:

```
string manyLines = @"This is line one
This is line two
Here is line three
The penultimate line is line four
This is the final, fifth line.";

using var reader = new StringReader(manyLines);
string? item;
do
{
    item = reader.ReadLine();
    Console.WriteLine(item);
} while (item != null);
```

Remarks

[File](#) and [Font](#) are examples of managed types that access unmanaged resources (in this case file handles and device contexts). There are many other kinds of unmanaged resources and class library types that encapsulate them. All such types must implement the [IDisposable](#) interface, or the [IAsyncDisposable](#) interface.

When the lifetime of an `IDisposable` object is limited to a single method, you should declare and instantiate it in the `using` statement. The `using` statement calls the [Dispose](#) method on the object in the correct way, and (when you use it as shown earlier) it also causes the object itself to go out of scope as soon as [Dispose](#) is called. Within the `using` block, the object is read-only and can't be modified or reassigned. If the object implements `IAsyncDisposable` instead of `IDisposable`, the `using` statement calls the [DisposeAsync](#) and `await`s the

returned [ValueTask](#). For more information on [IAsyncDisposable](#), see [Implement a DisposeAsync method](#).

The `using` statement ensures that [Dispose](#) (or [DisposeAsync](#)) is called even if an exception occurs within the `using` block. You can achieve the same result by putting the object inside a `try` block and then calling [Dispose](#) (or [DisposeAsync](#)) in a `finally` block; in fact, this is how the `using` statement is translated by the compiler. The code example earlier expands to the following code at compile time (note the extra curly braces to create the limited scope for the object):

```
string manyLines = @"This is line one
This is line two
Here is line three
The penultimate line is line four
This is the final, fifth line.";

{
    var reader = new StringReader(manyLines);
    try
    {
        string? item;
        do
        {
            item = reader.ReadLine();
            Console.WriteLine(item);
        } while (item != null);
    }
    finally
    {
        reader?.Dispose();
    }
}
```

The newer `using` statement syntax translates to similar code. The `try` block opens where the variable is declared. The `finally` block is added at the close of the enclosing block, typically at the end of a method.

For more information about the `try` - `finally` statement, see the [try-finally](#) article.

Multiple instances of a type can be declared in a single `using` statement, as shown in the following example. Notice that you can't use implicitly typed variables (`var`) when you declare multiple variables in a single statement:

```
string numbers = @"One
Two
Three
Four.";
string letters = @"A
B
C
D.";

using (StringReader left = new StringReader(numbers),
    right = new StringReader(letters))
{
    string? item;
    do
    {
        item = left.ReadLine();
        Console.Write(item);
        Console.Write(" ");
        item = right.ReadLine();
        Console.WriteLine(item);
    } while (item != null);
}
```

You can combine multiple declarations of the same type using the new syntax introduced with C# 8 as well, as shown in the following example:

```
string numbers = @"One
Two
Three
Four.";
string letters = @"A
B
C
D.";

using StringReader left = new StringReader(numbers),
    right = new StringReader(letters);
string? item;
do
{
    item = left.ReadLine();
    Console.Write(item);
    Console.Write(" ");
    item = right.ReadLine();
    Console.WriteLine(item);
} while (item != null);
```

You can instantiate the resource object and then pass the variable to the `using` statement, but this isn't a best practice. In this case, after control leaves the `using` block, the object remains in scope but probably has no access to its unmanaged resources. In other words, it's not fully initialized anymore. If you try to use the object outside the `using` block, you risk causing an exception to be thrown. For this reason, it's better to instantiate the object in the `using` statement and limit its scope to the `using` block.

```
string manyLines = @"This is line one
This is line two
Here is line three
The penultimate line is line four
This is the final, fifth line.";

var reader = new StringReader(manyLines);
using (reader)
{
    string? item;
    do
    {
        item = reader.ReadLine();
        Console.WriteLine(item);
    } while (item != null);
}
// reader is in scope here, but has been disposed
```

For more information about disposing of `IDisposable` objects, see [Using objects that implement IDisposable](#).

extern alias (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

You might have to reference two versions of assemblies that have the same fully-qualified type names. For example, you might have to use two or more versions of an assembly in the same application. By using an external assembly alias, the namespaces from each assembly can be wrapped inside root-level namespaces named by the alias, which enables them to be used in the same file.

NOTE

The `extern` keyword is also used as a method modifier, declaring a method written in unmanaged code.

To reference two assemblies with the same fully-qualified type names, an alias must be specified at a command prompt, as follows:

```
/r:GridV1=grid.dll
```

```
/r:GridV2=grid20.dll
```

This creates the external aliases `GridV1` and `GridV2`. To use these aliases from within a program, reference them by using the `extern` keyword. For example:

```
extern alias GridV1;
```

```
extern alias GridV2;
```

Each extern alias declaration introduces an additional root-level namespace that parallels (but does not lie within) the global namespace. Thus types from each assembly can be referred to without ambiguity by using their fully qualified name, rooted in the appropriate namespace-alias.

In the previous example, `GridV1::Grid` would be the grid control from `grid.dll`, and `GridV2::Grid` would be the grid control from `grid20.dll`.

Using Visual Studio

If you are using Visual Studio, aliases can be provided in similar way.

Add reference of `grid.dll` and `grid20.dll` to your project in Visual Studio. Open a property tab and change the Aliases from global to GridV1 and GridV2 respectively.

Use these aliases the same way above

```
extern alias GridV1;
```

```
extern alias GridV2;
```

Now you can create alias for a namespace or a type by *using alias directive*. For more information, see [using directive](#).

```
using Class1V1 = GridV1::Namespace.Class1;
```

```
using Class1V2 = GridV2::Namespace.Class1;
```

C# Language Specification

new constraint (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `new` constraint specifies that a type argument in a generic class declaration must have a public parameterless constructor. To use the `new` constraint, the type cannot be abstract.

Apply the `new` constraint to a type parameter when a generic class creates new instances of the type, as shown in the following example:

```
class ItemFactory<T> where T : new()
{
    public T GetNewItem()
    {
        return new T();
    }
}
```

When you use the `new()` constraint with other constraints, it must be specified last:

```
public class ItemFactory2<T>
    where T : IComparable, new()
{ }
```

For more information, see [Constraints on Type Parameters](#).

You can also use the `new` keyword to [create an instance of a type](#) or as a [member declaration modifier](#).

C# language specification

For more information, see the [Type parameter constraints](#) section of the [C# language specification](#).

where (generic type constraint) (C# Reference)

12/28/2021 • 5 minutes to read • [Edit Online](#)

The `where` clause in a generic definition specifies constraints on the types that are used as arguments for type parameters in a generic type, method, delegate, or local function. Constraints can specify interfaces, base classes, or require a generic type to be a reference, value, or unmanaged type. They declare capabilities that the type argument must have.

For example, you can declare a generic class, `AGenericClass`, such that the type parameter `T` implements the `IComparable<T>` interface:

```
public class AGenericClass<T> where T : IComparable<T> { }
```

NOTE

For more information on the `where` clause in a query expression, see [where clause](#).

The `where` clause can also include a base class constraint. The base class constraint states that a type to be used as a type argument for that generic type has the specified class as a base class, or is that base class. If the base class constraint is used, it must appear before any other constraints on that type parameter. Some types are disallowed as a base class constraint: `Object`, `Array`, and `ValueType`. Before C# 7.3, `Enum`, `Delegate`, and `MulticastDelegate` were also disallowed as base class constraints. The following example shows the types that can now be specified as a base class:

```
public class UsingEnum<T> where T : System.Enum { }

public class UsingDelegate<T> where T : System.Delegate { }

public class Multicaster<T> where T : System.MulticastDelegate { }
```

In a nullable context in C# 8.0 and later, the nullability of the base class type is enforced. If the base class is non-nullable (for example `Base`), the type argument must be non-nullable. If the base class is nullable (for example `Base?`), the type argument may be either a nullable or non-nullable reference type. The compiler issues a warning if the type argument is a nullable reference type when the base class is non-nullable.

The `where` clause can specify that the type is a `class` or a `struct`. The `struct` constraint removes the need to specify a base class constraint of `System.ValueType`. The `System.ValueType` type may not be used as a base class constraint. The following example shows both the `class` and `struct` constraints:

```
class MyClass<T, U>
    where T : class
    where U : struct
{ }
```

In a nullable context in C# 8.0 and later, the `class` constraint requires a type to be a non-nullable reference type. To allow nullable reference types, use the `class?` constraint, which allows both nullable and non-nullable reference types.

The `where` clause may include the `notnull` constraint. The `notnull` constraint limits the type parameter to

non-nullable types. The type may be a [value type](#) or a non-nullable reference type. The `notnull` constraint is available starting in C# 8.0 for code compiled in a `nullable enable` context. Unlike other constraints, if a type argument violates the `notnull` constraint, the compiler generates a warning instead of an error. Warnings are only generated in a `nullable enable` context.

The addition of nullable reference types introduces a potential ambiguity in the meaning of `T?` in generic methods. If `T` is a `struct`, `T?` is the same as `System.Nullable<T>`. However, if `T` is a reference type, `T?` means that `null` is a valid value. The ambiguity arises because overriding methods can't include constraints. The new `default` constraint resolves this ambiguity. You'll add it when a base class or interface declares two overloads of a method, one that specifies the `struct` constraint, and one that doesn't have either the `struct` or `class` constraint applied:

```
public abstract class B
{
    public void M<T>(T? item) where T : struct { }
    public abstract void M<T>(T? item);
}
```

You use the `default` constraint to specify that your derived class overrides the method without the constraint in your derived class, or explicit interface implementation. It's only valid on methods that override base methods, or explicit interface implementations:

```
public class D : B
{
    // Without the "default" constraint, the compiler tries to override the first method in B
    public override void M<T>(T? item) where T : default { }
```

IMPORTANT

Generic declarations that include the `notnull` constraint can be used in a nullable oblivious context, but compiler does not enforce the constraint.

```
#nullable enable
class NotNullContainer<T>
    where T : notnull
{
}
#nullable restore
```

The `where` clause may also include an `unmanaged` constraint. The `unmanaged` constraint limits the type parameter to types known as [unmanaged types](#). The `unmanaged` constraint makes it easier to write low-level interop code in C#. This constraint enables reusable routines across all unmanaged types. The `unmanaged` constraint can't be combined with the `class` or `struct` constraint. The `unmanaged` constraint enforces that the type must be a `struct`:

```
class UnManagedWrapper<T>
    where T : unmanaged
{ }
```

The `where` clause may also include a constructor constraint, `new()`. That constraint makes it possible to create an instance of a type parameter using the `new` operator. The [new\(\) Constraint](#) lets the compiler know that any

type argument supplied must have an accessible parameterless constructor. For example:

```
public class MyGenericClass<T> where T : IComparable<T>, new()
{
    // The following line is not possible without new() constraint:
    T item = new T();
}
```

The `new()` constraint appears last in the `where` clause. The `new()` constraint can't be combined with the `struct` or `unmanaged` constraints. All types satisfying those constraints must have an accessible parameterless constructor, making the `new()` constraint redundant.

With multiple type parameters, use one `where` clause for each type parameter, for example:

```
public interface IMyInterface { }

namespace CodeExample
{
    class Dictionary<TKey, TVal>
        where TKey : IComparable<TKey>
        where TVal : IMyInterface
    {
        public void Add(TKey key, TVal val) { }
    }
}
```

You can also attach constraints to type parameters of generic methods, as shown in the following example:

```
public void MyMethod<T>(T t) where T : IMyInterface { }
```

Notice that the syntax to describe type parameter constraints on delegates is the same as that of methods:

```
delegate T MyDelegate<T>() where T : new();
```

For information on generic delegates, see [Generic Delegates](#).

For details on the syntax and use of constraints, see [Constraints on Type Parameters](#).

C# language specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

base (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `base` keyword is used to access members of the base class from within a derived class:

- Call a method on the base class that has been overridden by another method.
- Specify which base-class constructor should be called when creating instances of the derived class.

A base class access is permitted only in a constructor, an instance method, or an instance property accessor.

It is an error to use the `base` keyword from within a static method.

The base class that is accessed is the base class specified in the class declaration. For example, if you specify `class ClassB : ClassA`, the members of ClassA are accessed from ClassB, regardless of the base class of ClassA.

Example 1

In this example, both the base class, `Person`, and the derived class, `Employee`, have a method named `Getinfo`. By using the `base` keyword, it is possible to call the `Getinfo` method on the base class, from within the derived class.

```

public class Person
{
    protected string ssn = "444-55-6666";
    protected string name = "John L. Malgraine";

    public virtual void GetInfo()
    {
        Console.WriteLine("Name: {0}", name);
        Console.WriteLine("SSN: {0}", ssn);
    }
}

class Employee : Person
{
    public string id = "ABC567EFG";
    public override void GetInfo()
    {
        // Calling the base class GetInfo method:
        base.GetInfo();
        Console.WriteLine("Employee ID: {0}", id);
    }
}

class TestClass
{
    static void Main()
    {
        Employee E = new Employee();
        E.GetInfo();
    }
}
/*
Output
Name: John L. Malgraine
SSN: 444-55-6666
Employee ID: ABC567EFG
*/

```

For additional examples, see [new](#), [virtual](#), and [override](#).

Example 2

This example shows how to specify the base-class constructor called when creating instances of a derived class.

```

public class BaseClass
{
    int num;

    public BaseClass()
    {
        Console.WriteLine("in BaseClass()");
    }

    public BaseClass(int i)
    {
        num = i;
        Console.WriteLine("in BaseClass(int i)");
    }

    public int GetNum()
    {
        return num;
    }
}

public class DerivedClass : BaseClass
{
    // This constructor will call BaseClass.BaseClass()
    public DerivedClass() : base()
    {
    }

    // This constructor will call BaseClass.BaseClass(int i)
    public DerivedClass(int i) : base(i)
    {
    }

    static void Main()
    {
        DerivedClass md = new DerivedClass();
        DerivedClass md1 = new DerivedClass(1);
    }
}
/*
Output:
in BaseClass()
in BaseClass(int i)
*/

```

- [C# Keywords](#)
- [this](#)

this (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `this` keyword refers to the current instance of the class and is also used as a modifier of the first parameter of an extension method.

NOTE

This article discusses the use of `this` with class instances. For more information about its use in extension methods, see [Extension Methods](#).

The following are common uses of `this`:

- To qualify members hidden by similar names, for example:

```
public class Employee
{
    private string alias;
    private string name;

    public Employee(string name, string alias)
    {
        // Use this to qualify the members of the class
        // instead of the constructor parameters.
        this.name = name;
        this.alias = alias;
    }
}
```

- To pass an object as a parameter to other methods, for example:

```
CalcTax(this);
```

- To declare indexers, for example:

```
public int this[int param]
{
    get { return array[param]; }
    set { array[param] = value; }
}
```

Static member functions, because they exist at the class level and not as part of an object, do not have a `this` pointer. It is an error to refer to `this` in a static method.

Example

In this example, `this` is used to qualify the `Employee` class members, `name` and `alias`, which are hidden by similar names. It is also used to pass an object to the method `CalcTax`, which belongs to another class.

```

class Employee
{
    private string name;
    private string alias;
    private decimal salary = 3000.00m;

    // Constructor:
    public Employee(string name, string alias)
    {
        // Use this to qualify the fields, name and alias:
        this.name = name;
        this.alias = alias;
    }

    // Printing method:
    public void printEmployee()
    {
        Console.WriteLine("Name: {0}\nAlias: {1}", name, alias);
        // Passing the object to the CalcTax method by using this:
        Console.WriteLine("Taxes: {0:C}", Tax.CalcTax(this));
    }

    public decimal Salary
    {
        get { return salary; }
    }
}

class Tax
{
    public static decimal CalcTax(Employee E)
    {
        return 0.08m * E.Salary;
    }
}

class MainClass
{
    static void Main()
    {
        // Create objects:
        Employee E1 = new Employee("Mingda Pan", "mpan");

        // Display results:
        E1.printEmployee();
    }
}
/*
Output:
    Name: Mingda Pan
    Alias: mpan
    Taxes: $240.00
*/

```

null (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `null` keyword is a literal that represents a null reference, one that does not refer to any object. `null` is the default value of reference-type variables. Ordinary value types cannot be null, except for [nullable value types](#).

The following example demonstrates some behaviors of the `null` keyword:

```

class Program
{
    class MyClass
    {
        public void MyMethod() { }
    }

    static void Main(string[] args)
    {
        // Set a breakpoint here to see that mc = null.
        // However, the compiler considers it "unassigned."
        // and generates a compiler error if you try to
        // use the variable.
        MyClass mc;

        // Now the variable can be used, but...
        mc = null;

        // ... a method call on a null object raises
        // a run-time NullReferenceException.
        // Uncomment the following line to see for yourself.
        // mc.MyMethod();

        // Now mc has a value.
        mc = new MyClass();

        // You can call its method.
        mc.MyMethod();

        // Set mc to null again. The object it referenced
        // is no longer accessible and can now be garbage-collected.
        mc = null;

        // A null string is not the same as an empty string.
        string s = null;
        string t = String.Empty; // Logically the same as ""

        // Equals applied to any null object returns false.
        bool b = (t.Equals(s));
        Console.WriteLine(b);

        // Equality operator also returns false when one
        // operand is null.
        Console.WriteLine("Empty string {0} null string", s == t ? "equals": "does not equal");

        // Returns true.
        Console.WriteLine("null == null is {0}", null == null);

        // A value type cannot be null
        // int i = null; // Compiler error!

        // Use a nullable value type instead:
        int? i = null;

        // Keep the console window open in debug mode.
        System.Console.WriteLine("Press any key to exit.");
        System.Console.ReadKey();
    }
}

```

bool (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `bool` type keyword is an alias for the .NET [System.Boolean](#) structure type that represents a Boolean value, which can be either `true` or `false`.

To perform logical operations with values of the `bool` type, use [Boolean logical](#) operators. The `bool` type is the result type of [comparison](#) and [equality](#) operators. A `bool` expression can be a controlling conditional expression in the [if](#), [do](#), [while](#), and [for](#) statements and in the [conditional operator](#) `?:`.

The default value of the `bool` type is `false`.

Literals

You can use the `true` and `false` literals to initialize a `bool` variable or to pass a `bool` value:

```
bool check = true;
Console.WriteLine(check ? "Checked" : "Not checked"); // output: Checked

Console.WriteLine(false ? "Checked" : "Not checked"); // output: Not checked
```

Three-valued Boolean logic

Use the nullable `bool?` type, if you need to support the three-valued logic, for example, when you work with databases that support a three-valued Boolean type. For the `bool?` operands, the predefined `&` and `|` operators support the three-valued logic. For more information, see the [Nullable Boolean logical operators](#) section of the [Boolean logical operators](#) article.

For more information about nullable value types, see [Nullable value types](#).

Conversions

C# provides only two conversions that involve the `bool` type. Those are an implicit conversion to the corresponding nullable `bool?` type and an explicit conversion from the `bool?` type. However, .NET provides additional methods that you can use to convert to or from the `bool` type. For more information, see the [Converting to and from Boolean values](#) section of the [System.Boolean](#) API reference page.

C# language specification

For more information, see [The bool type](#) section of the [C# language specification](#).

default (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

You can use the `default` keyword in the following contexts:

- To specify the default case in the `switch` statement.
- As the [default operator or literal](#) to produce the default value of a type.
- As the `default` [type constraint](#) on a generic method override or explicit interface implementation.

See also

- [C# reference](#)
- [C# keywords](#)

Contextual keywords (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

A contextual keyword is used to provide a specific meaning in the code, but it is not a reserved word in C#. The following contextual keywords are introduced in this section:

KEYWORD	DESCRIPTION
<code>add</code>	Defines a custom event accessor that is invoked when client code subscribes to the event.
<code>and</code>	Creates a pattern that matches when both of nested patterns match.
<code>async</code>	Indicates that the modified method, lambda expression, or anonymous method is asynchronous.
<code>await</code>	Suspends an async method until an awaited task is completed.
<code>dynamic</code>	Defines a reference type that enables operations in which it occurs to bypass compile-time type checking.
<code>get</code>	Defines an accessor method for a property or an indexer.
<code>global</code>	Alias of the global namespace, which is otherwise unnamed.
<code>init</code>	Defines an accessor method for a property or an indexer.
<code>nint</code>	Defines a native-sized integer data type.
<code>not</code>	Creates a pattern that matches when the negated pattern doesn't match.
<code>nuint</code>	Defines a native-sized unsigned integer data type.
<code>or</code>	Creates a pattern that matches when either of nested patterns matches.
<code>partial</code>	Defines partial classes, structs, and interfaces throughout the same compilation unit.
<code>record</code>	Used to define a record type.
<code>remove</code>	Defines a custom event accessor that is invoked when client code unsubscribes from the event.
<code>set</code>	Defines an accessor method for a property or an indexer.
<code>value</code>	Used to set accessors and to add or remove event handlers.

KEYWORD	DESCRIPTION
var	Enables the type of a variable declared at method scope to be determined by the compiler.
when	Specifies a filter condition for a <code>catch</code> block or the <code>case</code> label of a <code>switch</code> statement.
where	Adds constraints to a generic declaration. (See also where).
yield	Used in an iterator block to return a value to the enumerator object or to signal the end of iteration.

All query keywords introduced in C# 3.0 are also contextual. For more information, see [Query Keywords \(LINQ\)](#).

See also

- [C# reference](#)
- [C# keywords](#)
- [C# operators and expressions](#)

add (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `add` contextual keyword is used to define a custom event accessor that is invoked when client code subscribes to your [event](#). If you supply a custom `add` accessor, you must also supply a [remove](#) accessor.

Example

The following example shows an event that has custom `add` and [remove](#) accessors. For the full example, see [How to implement interface events](#).

```
class Events : IDrawingObject
{
    event EventHandler PreDrawEvent;

    event EventHandler IDrawingObject.OnDraw
    {
        add => PreDrawEvent += value;
        remove => PreDrawEvent -= value;
    }
}
```

You do not typically need to provide your own custom event accessors. The accessors that are automatically generated by the compiler when you declare an event are sufficient for most scenarios.

See also

- [Events](#)

get (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `get` keyword defines an *accessor* method in a property or indexer that returns the property value or the indexer element. For more information, see [Properties](#), [Auto-Implemented Properties](#) and [Indexers](#).

The following example defines both a `get` and a `set` accessor for a property named `Seconds`. It uses a private field named `_seconds` to back the property value.

```
class TimePeriod
{
    private double _seconds;

    public double Seconds
    {
        get { return _seconds; }
        set { _seconds = value; }
    }
}
```

Often, the `get` accessor consists of a single statement that returns a value, as it did in the previous example. Starting with C# 7.0, you can implement the `get` accessor as an expression-bodied member. The following example implements both the `get` and the `set` accessor as expression-bodied members.

```
class TimePeriod
{
    private double _seconds;

    public double Seconds
    {
        get => _seconds;
        set => _seconds = value;
    }
}
```

For simple cases in which a property's `get` and `set` accessors perform no other operation than setting or retrieving a value in a private backing field, you can take advantage of the C# compiler's support for auto-implemented properties. The following example implements `Hours` as an auto-implemented property.

```
class TimePeriod2
{
    public double Hours { get; set; }
}
```

C# Language Specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

See also

- [C# Reference](#)
- [C# Programming Guide](#)
- [C# Keywords](#)
- [Properties](#)

init (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

In C# 9 and later, the `init` keyword defines an *accessor* method in a property or indexer. An init-only setter assigns a value to the property or the indexer element only during object construction. For more information and examples, see [Properties](#), [Auto-Implemented Properties](#), and [Indexers](#).

The following example defines both a `get` and an `init` accessor for a property named `Seconds`. It uses a private field named `_seconds` to back the property value.

```
class InitExample
{
    private double _seconds;

    public double Seconds
    {
        get { return _seconds; }
        init { _seconds = value; }
    }
}
```

Often, the `init` accessor consists of a single statement that assigns a value, as it did in the previous example. You can implement the `init` accessor as an expression-bodied member. The following example implements both the `get` and the `init` accessors as expression-bodied members.

```
class InitExampleExpressionBodied
{
    private double _seconds;

    public double Seconds
    {
        get => _seconds;
        init => _seconds = value;
    }
}
```

For simple cases in which a property's `get` and `init` accessors perform no other operation than setting or retrieving a value in a private backing field, you can take advantage of the C# compiler's support for auto-implemented properties. The following example implements `Hours` as an auto-implemented property.

```
class InitExampleAutoProperty
{
    public double Hours { get; init; }
}
```

C# language specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

See also

- [C# Reference](#)
- [C# Programming Guide](#)
- [C# Keywords](#)
- [Properties](#)

partial type (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Partial type definitions allow for the definition of a class, struct, interface, or record to be split into multiple files.

In *File1.cs*:

```
namespace PC
{
    partial class A
    {
        int num = 0;
        void MethodA() { }
        partial void MethodC();
    }
}
```

In *File2.cs* the declaration:

```
namespace PC
{
    partial class A
    {
        void MethodB() { }
        partial void MethodC() { }
    }
}
```

Remarks

Splitting a class, struct or interface type over several files can be useful when you are working with large projects, or with automatically generated code such as that provided by the [Windows Forms Designer](#). A partial type may contain a [partial method](#). For more information, see [Partial Classes and Methods](#).

C# language specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

See also

- [C# Reference](#)
- [C# Programming Guide](#)
- [Modifiers](#)
- [Introduction to Generics](#)

partial method (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

A partial method has its signature defined in one part of a partial type, and its implementation defined in another part of the type. Partial methods enable class designers to provide method hooks, similar to event handlers, that developers may decide to implement or not. If the developer does not supply an implementation, the compiler removes the signature at compile time. The following conditions apply to partial methods:

- Declarations must begin with the contextual keyword [partial](#).
- Signatures in both parts of the partial type must match.

A partial method isn't required to have an implementation in the following cases:

- It doesn't have any accessibility modifiers (including the default [private](#)).
- It returns [void](#).
- It doesn't have any [out](#) parameters.
- It doesn't have any of the following modifiers [virtual](#), [override](#), [sealed](#), [new](#), or [extern](#).

Any method that doesn't conform to all those restrictions (for example, `public virtual partial void method()`), must provide an implementation.

The following example shows a partial method defined in two parts of a partial class:

```
namespace PM
{
    partial class A
    {
        partial void OnSomethingHappened(string s);
    }

    // This part can be in a separate file.
    partial class A
    {
        // Comment out this method and the program
        // will still compile.
        partial void OnSomethingHappened(String s)
        {
            Console.WriteLine("Something happened: {0}", s);
        }
    }
}
```

Partial methods can also be useful in combination with source generators. For example a regex could be defined using the following pattern:

```
[RegexGenerated("(dog|cat|fish)")]
partial bool IsPetMatch(string input);
```

For more information, see [Partial Classes and Methods](#).

See also

- [C# Reference](#)
- [partial type](#)

remove (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `remove` contextual keyword is used to define a custom event accessor that is invoked when client code unsubscribes from your [event](#). If you supply a custom `remove` accessor, you must also supply an `add` accessor.

Example

The following example shows an event with custom `add` and `remove` accessors. For the full example, see [How to implement interface events](#).

```
class Events : IDrawingObject
{
    event EventHandler PreDrawEvent;

    event EventHandler IDrawingObject.OnDraw
    {
        add => PreDrawEvent += value;
        remove => PreDrawEvent -= value;
    }
}
```

You do not typically need to provide your own custom event accessors. The accessors that are automatically generated by the compiler when you declare an event are sufficient for most scenarios.

See also

- [Events](#)

set (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `set` keyword defines an *accessor* method in a property or indexer that assigns a value to the property or the indexer element. For more information and examples, see [Properties](#), [Auto-Implemented Properties](#), and [Indexers](#).

The following example defines both a `get` and a `set` accessor for a property named `Seconds`. It uses a private field named `_seconds` to back the property value.

```
class TimePeriod
{
    private double _seconds;

    public double Seconds
    {
        get { return _seconds; }
        set { _seconds = value; }
    }
}
```

Often, the `set` accessor consists of a single statement that assigns a value, as it did in the previous example. Starting with C# 7.0, you can implement the `set` accessor as an expression-bodied member. The following example implements both the `get` and the `set` accessors as expression-bodied members.

```
class TimePeriod
{
    private double _seconds;

    public double Seconds
    {
        get => _seconds;
        set => _seconds = value;
    }
}
```

For simple cases in which a property's `get` and `set` accessors perform no other operation than setting or retrieving a value in a private backing field, you can take advantage of the C# compiler's support for auto-implemented properties. The following example implements `Hours` as an auto-implemented property.

```
class TimePeriod2
{
    public double Hours { get; set; }
}
```

C# language specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

See also

- [C# Reference](#)
- [C# Programming Guide](#)
- [C# Keywords](#)
- [Properties](#)

when (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

You use the `when` contextual keyword to specify a filter condition in the following contexts:

- In the `catch` statement of a `try/catch` or `try/catch/finally` block.
- As a `case guard` in the `switch` statement.
- As a `case guard` in the `switch` expression.

`when` in a `catch` statement

Starting with C# 6, `when` can be used in a `catch` statement to specify a condition that must be true for the handler for a specific exception to execute. Its syntax is:

```
catch (ExceptionType [e]) when (expr)
```

where *expr* is an expression that evaluates to a Boolean value. If it returns `true`, the exception handler executes; if `false`, it does not.

The following example uses the `when` keyword to conditionally execute handlers for an `HttpRequestException` depending on the text of the exception message.

```
using System;
using System.Net.Http;
using System.Threading.Tasks;

class Program
{
    static void Main()
    {
        Console.WriteLine(MakeRequest().Result);
    }

    public static async Task<string> MakeRequest()
    {
        var client = new HttpClient();
        var streamTask = client.GetStringAsync("https://localhost:10000");
        try
        {
            var responseText = await streamTask;
            return responseText;
        }
        catch (HttpRequestException e) when (e.Message.Contains("301"))
        {
            return "Site Moved";
        }
        catch (HttpRequestException e) when (e.Message.Contains("404"))
        {
            return "Page Not Found";
        }
        catch (HttpRequestException e)
        {
            return e.Message;
        }
    }
}
```

See also

- [try/catch statement](#)
- [try/catch/finally statement](#)

value (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The contextual keyword `value` is used in the `set` accessor in [property](#) and [indexer](#) declarations. It is similar to an input parameter of a method. The word `value` references the value that client code is attempting to assign to the property or indexer. In the following example, `MyDerivedClass` has a property called `Name` that uses the `value` parameter to assign a new string to the backing field `_name`. From the point of view of client code, the operation is written as a simple assignment.

```
class MyBaseClass
{
    // virtual auto-implemented property. Overrides can only
    // provide specialized behavior if they implement get and set accessors.
    public virtual string Name { get; set; }

    // ordinary virtual property with backing field
    private int _num;
    public virtual int Number
    {
        get { return _num; }
        set { _num = value; }
    }
}

class MyDerivedClass : MyBaseClass
{
    private string _name;

    // Override auto-implemented property with ordinary property
    // to provide specialized accessor behavior.
    public override string Name
    {
        get
        {
            return _name;
        }
        set
        {
            if (!string.IsNullOrEmpty(value))
            {
                _name = value;
            }
            else
            {
                _name = "Unknown";
            }
        }
    }
}
```

For more information, see the [Properties](#) and [Indexers](#) articles.

C# language specification

For more information, see the [C# Language Specification](#). The language specification is the definitive source for C# syntax and usage.

- [C# Reference](#)
- [C# Programming Guide](#)
- [C# Keywords](#)

yield (C# Reference)

12/28/2021 • 5 minutes to read • [Edit Online](#)

When you use the `yield` [contextual keyword](#) in a statement, you indicate that the method, operator, or `get` accessor in which it appears is an iterator. Using `yield` to define an iterator removes the need for an explicit extra class (the class that holds the state for an enumeration, see [IEnumerator<T>](#) for an example) when you implement the [IEnumerable](#) and [IEnumerator](#) pattern for a custom collection type.

The following example shows the two forms of the `yield` statement.

```
yield return <expression>;  
yield break;
```

Remarks

You use a `yield return` statement to return each element one at a time.

The sequence returned from an iterator method can be consumed by using a [foreach](#) statement or LINQ query. Each iteration of the `foreach` loop calls the iterator method. When a `yield return` statement is reached in the iterator method, `expression` is returned, and the current location in code is retained. Execution is restarted from that location the next time that the iterator function is called.

When the iterator returns an [System.Collections.Generic.IAsyncEnumerable<T>](#), that sequence can be consumed asynchronously using an [await foreach](#) statement. The iteration of the loop is analogous to the `foreach` statement. The difference is that each iteration may be suspended for an asynchronous operation before returning the expression for the next element.

You can use a `yield break` statement to end the iteration.

For more information about iterators, see [Iterators](#).

Iterator methods and get accessors

The declaration of an iterator must meet the following requirements:

- The return type must be one of the following types:
 - [IAsyncEnumerable<T>](#)
 - [IEnumerable<T>](#)
 - [IEnumerable](#)
 - [IEnumerator<T>](#)
 - [IEnumerator](#)
- The declaration can't have any [in](#), [ref](#), or [out](#) parameters.

The `yield` type of an iterator that returns [IEnumerable](#) or [IEnumerator](#) is `object`. If the iterator returns [IEnumerable<T>](#) or [IEnumerator<T>](#), there must be an implicit conversion from the type of the expression in the `yield return` statement to the generic type parameter.

You can't include a `yield return` or `yield break` statement in:

- [Lambda expressions](#) and [anonymous methods](#).
- Methods that contain unsafe blocks. For more information, see [unsafe](#).

Exception handling

A `yield return` statement can't be located in a try-catch block. A `yield return` statement can be located in the try block of a try-finally statement.

A `yield break` statement can be located in a try block or a catch block but not a finally block.

If the `foreach` or `await foreach` body (outside of the iterator method) throws an exception, a `finally` block in the iterator method is executed.

Technical implementation

The following code returns an `IEnumerable<string>` from an iterator method and then iterates through its elements.

```
IEnumerable<string> elements = MyIteratorMethod();
foreach (string element in elements)
{
    ...
}
```

The call to `MyIteratorMethod` doesn't execute the body of the method. Instead the call returns an `IEnumerable<string>` into the `elements` variable.

On an iteration of the `foreach` loop, the `MoveNext` method is called for `elements`. This call executes the body of `MyIteratorMethod` until the next `yield return` statement is reached. The expression returned by the `yield return` statement determines not only the value of the `element` variable for consumption by the loop body but also the `Current` property of `elements`, which is an `IEnumerator<string>`.

On each subsequent iteration of the `foreach` loop, the execution of the iterator body continues from where it left off, again stopping when it reaches a `yield return` statement. The `foreach` loop completes when the end of the iterator method or a `yield break` statement is reached.

The following code returns an `IAsyncEnumerable<string>` from an iterator method and then iterates through its elements.

```
IAsyncEnumerable<string> elements = MyAsyncIteratorMethod();
await foreach (string element in elements)
{
    // ...
}
```

On an iteration of the `await foreach` loop, the `IAsyncEnumerator<T>.MoveNextAsync` method is called for `elements`. The `System.Threading.Tasks.ValueTask<TResult>` return by `MoveNext` completes when the next `yield return` is reached.

On each subsequent iteration of the `await foreach` loop, the execution of the iterator body continues from where it left off, again stopping when it reaches a `yield return` statement. The `await foreach` loop completes when the end of the iterator method or a `yield break` statement is reached.

Examples

The following example has a `yield return` statement that's inside a `for` loop. Each iteration of the `foreach` statement body in the `Main` method creates a call to the `Power` iterator function. Each call to the iterator function proceeds to the next execution of the `yield return` statement, which occurs during the next iteration of

the `for` loop.

The return type of the iterator method is `IEnumerable`, which is an iterator interface type. When the iterator method is called, it returns an enumerable object that contains the powers of a number.

```
public class PowersOf2
{
    static void Main()
    {
        // Display powers of 2 up to the exponent of 8:
        foreach (int i in Power(2, 8))
        {
            Console.Write("{0} ", i);
        }
    }

    public static System.Collections.Generic.IEnumerable<int> Power(int number, int exponent)
    {
        int result = 1;

        for (int i = 0; i < exponent; i++)
        {
            result = result * number;
            yield return result;
        }
    }

    // Output: 2 4 8 16 32 64 128 256
}
```

The following example demonstrates a `get` accessor that is an iterator. In the example, each `yield return` statement returns an instance of a user-defined class.

```

public static class GalaxyClass
{
    public static void ShowGalaxies()
    {
        var theGalaxies = new Galaxies();
        foreach (Galaxy theGalaxy in theGalaxies.NextGalaxy)
        {
            Debug.WriteLine(theGalaxy.Name + " " + theGalaxy.MegaLightYears.ToString());
        }
    }

    public class Galaxies
    {
        public System.Collections.Generic.IEnumerable<Galaxy> NextGalaxy
        {
            get
            {
                yield return new Galaxy { Name = "Tadpole", MegaLightYears = 400 };
                yield return new Galaxy { Name = "Pinwheel", MegaLightYears = 25 };
                yield return new Galaxy { Name = "Milky Way", MegaLightYears = 0 };
                yield return new Galaxy { Name = "Andromeda", MegaLightYears = 3 };
            }
        }
    }

    public class Galaxy
    {
        public String Name { get; set; }
        public int MegaLightYears { get; set; }
    }
}

```

Query keywords (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

This section contains the contextual keywords used in query expressions.

In this section

CLAUSE	DESCRIPTION
from	Specifies a data source and a range variable (similar to an iteration variable).
where	Filters source elements based on one or more Boolean expressions separated by logical AND and OR operators (<code>&&</code> or <code> </code>).
select	Specifies the type and shape that the elements in the returned sequence will have when the query is executed.
group	Groups query results according to a specified key value.
into	Provides an identifier that can serve as a reference to the results of a join, group or select clause.
orderby	Sorts query results in ascending or descending order based on the default comparer for the element type.
join	Joins two data sources based on an equality comparison between two specified matching criteria.
let	Introduces a range variable to store sub-expression results in a query expression.
in	Contextual keyword in a join clause.
on	Contextual keyword in a join clause.
equals	Contextual keyword in a join clause.
by	Contextual keyword in a group clause.
ascending	Contextual keyword in an orderby clause.
descending	Contextual keyword in an orderby clause.

from clause (C# Reference)

12/28/2021 • 5 minutes to read • [Edit Online](#)

A query expression must begin with a `from` clause. Additionally, a query expression can contain sub-queries, which also begin with a `from` clause. The `from` clause specifies the following:

- The data source on which the query or sub-query will be run.
- A local *range variable* that represents each element in the source sequence.

Both the range variable and the data source are strongly typed. The data source referenced in the `from` clause must have a type of `IEnumerable`, `IEnumerable<T>`, or a derived type such as `IQueryable<T>`.

In the following example, `numbers` is the data source and `num` is the range variable. Note that both variables are strongly typed even though the `var` keyword is used.

```
class LowNums
{
    static void Main()
    {
        // A simple data source.
        int[] numbers = { 5, 4, 1, 3, 9, 8, 6, 7, 2, 0 };

        // Create the query.
        // lowNums is an IEnumerable<int>
        var lowNums = from num in numbers
                      where num < 5
                      select num;

        // Execute the query.
        foreach (int i in lowNums)
        {
            Console.Write(i + " ");
        }
    }
}
// Output: 4 1 3 2 0
```

The range variable

The compiler infers the type of the range variable when the data source implements `IEnumerable<T>`. For example, if the source has a type of `IEnumerable<Customer>`, then the range variable is inferred to be `Customer`. The only time that you must specify the type explicitly is when the source is a non-generic `IEnumerable` type such as `ArrayList`. For more information, see [How to query an ArrayList with LINQ](#).

In the previous example `num` is inferred to be of type `int`. Because the range variable is strongly typed, you can call methods on it or use it in other operations. For example, instead of writing `select num`, you could write `select num.ToString()` to cause the query expression to return a sequence of strings instead of integers. Or you could write `select num + 10` to cause the expression to return the sequence 14, 11, 13, 12, 10. For more information, see [select clause](#).

The range variable is like an iteration variable in a `foreach` statement except for one very important difference: a range variable never actually stores data from the source. It's just a syntactic convenience that enables the query to describe what will occur when the query is executed. For more information, see [Introduction to LINQ Queries \(C#\)](#).

Compound from clauses

In some cases, each element in the source sequence may itself be either a sequence or contain a sequence. For example, your data source may be an `IEnumerable<Student>` where each student object in the sequence contains a list of test scores. To access the inner list within each `Student` element, you can use compound `from` clauses. The technique is like using nested `foreach` statements. You can add `where` or `orderby` clauses to either `from` clause to filter the results. The following example shows a sequence of `Student` objects, each of which contains an inner `List` of integers representing test scores. To access the inner list, use a compound `from` clause. You can insert clauses between the two `from` clauses if necessary.

```

class CompoundFrom
{
    // The element type of the data source.
    public class Student
    {
        public string LastName { get; set; }
        public List<int> Scores {get; set;}
    }

    static void Main()
    {
        // Use a collection initializer to create the data source. Note that
        // each element in the list contains an inner sequence of scores.
        List<Student> students = new List<Student>
        {
            new Student {LastName="Omelchenko", Scores= new List<int> {97, 72, 81, 60}},
            new Student {LastName="O'Donnell", Scores= new List<int> {75, 84, 91, 39}},
            new Student {LastName="Mortensen", Scores= new List<int> {88, 94, 65, 85}},
            new Student {LastName="Garcia", Scores= new List<int> {97, 89, 85, 82}},
            new Student {LastName="Beebe", Scores= new List<int> {35, 72, 91, 70}}
        };

        // Use a compound from to access the inner sequence within each element.
        // Note the similarity to a nested foreach statement.
        var scoreQuery = from student in students
                        from score in student.Scores
                        where score > 90
                        select new { Last = student.LastName, score };

        // Execute the queries.
        Console.WriteLine("scoreQuery:");
        // Rest the mouse pointer on scoreQuery in the following line to
        // see its type. The type is IEnumerable<'a>, where 'a is an
        // anonymous type defined as new {string Last, int score}. That is,
        // each instance of this anonymous type has two members, a string
        // (Last) and an int (score).
        foreach (var student in scoreQuery)
        {
            Console.WriteLine("{0} Score: {1}", student.Last, student.score);
        }

        // Keep the console window open in debug mode.
        Console.WriteLine("Press any key to exit.");
        Console.ReadKey();
    }
}
/*
scoreQuery:
Omelchenko Score: 97
O'Donnell Score: 91
Mortensen Score: 94
Garcia Score: 97
Beebe Score: 91
*/

```

Using Multiple from Clauses to Perform Joins

A compound `from` clause is used to access inner collections in a single data source. However, a query can also contain multiple `from` clauses that generate supplemental queries from independent data sources. This technique enables you to perform certain types of join operations that are not possible by using the [join clause](#).

The following example shows how two `from` clauses can be used to form a complete cross join of two data sources.

```

class CompoundFrom2
{
    static void Main()
    {
        char[] upperCase = { 'A', 'B', 'C' };
        char[] lowerCase = { 'x', 'y', 'z' };

        // The type of joinQuery1 is IEnumerable<'a>, where 'a
        // indicates an anonymous type. This anonymous type has two
        // members, upper and lower, both of type char.
        var joinQuery1 =
            from upper in upperCase
            from lower in lowerCase
            select new { upper, lower };

        // The type of joinQuery2 is IEnumerable<'a>, where 'a
        // indicates an anonymous type. This anonymous type has two
        // members, upper and lower, both of type char.
        var joinQuery2 =
            from lower in lowerCase
            where lower != 'x'
            from upper in upperCase
            select new { lower, upper };

        // Execute the queries.
        Console.WriteLine("Cross join:");
        // Rest the mouse pointer on joinQuery1 to verify its type.
        foreach (var pair in joinQuery1)
        {
            Console.WriteLine("{0} is matched to {1}", pair.upper, pair.lower);
        }

        Console.WriteLine("Filtered non-equijoin:");
        // Rest the mouse pointer over joinQuery2 to verify its type.
        foreach (var pair in joinQuery2)
        {
            Console.WriteLine("{0} is matched to {1}", pair.lower, pair.upper);
        }

        // Keep the console window open in debug mode.
        Console.WriteLine("Press any key to exit.");
        Console.ReadKey();
    }
}
/* Output:
Cross join:
A is matched to x
A is matched to y
A is matched to z
B is matched to x
B is matched to y
B is matched to z
C is matched to x
C is matched to y
C is matched to z
Filtered non-equijoin:
y is matched to A
y is matched to B
y is matched to C
z is matched to A
z is matched to B
z is matched to C
*/

```

where clause (C# Reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

The `where` clause is used in a query expression to specify which elements from the data source will be returned in the query expression. It applies a Boolean condition (*predicate*) to each source element (referenced by the range variable) and returns those for which the specified condition is true. A single query expression may contain multiple `where` clauses and a single clause may contain multiple predicate subexpressions.

Example 1

In the following example, the `where` clause filters out all numbers except those that are less than five. If you remove the `where` clause, all numbers from the data source would be returned. The expression `num < 5` is the predicate that is applied to each element.

```
class WhereSample
{
    static void Main()
    {
        // Simple data source. Arrays support IEnumerable<T>.
        int[] numbers = { 5, 4, 1, 3, 9, 8, 6, 7, 2, 0 };

        // Simple query with one predicate in where clause.
        var queryLowNums =
            from num in numbers
            where num < 5
            select num;

        // Execute the query.
        foreach (var s in queryLowNums)
        {
            Console.Write(s.ToString() + " ");
        }
    }
}
//Output: 4 1 3 2 0
```

Example 2

Within a single `where` clause, you can specify as many predicates as necessary by using the `&&` and `||` operators. In the following example, the query specifies two predicates in order to select only the even numbers that are less than five.

```

class WhereSample2
{
    static void Main()
    {
        // Data source.
        int[] numbers = { 5, 4, 1, 3, 9, 8, 6, 7, 2, 0 };

        // Create the query with two predicates in where clause.
        var queryLowNums2 =
            from num in numbers
            where num < 5 && num % 2 == 0
            select num;

        // Execute the query
        foreach (var s in queryLowNums2)
        {
            Console.Write(s.ToString() + " ");
        }
        Console.WriteLine();

        // Create the query with two where clause.
        var queryLowNums3 =
            from num in numbers
            where num < 5
            where num % 2 == 0
            select num;

        // Execute the query
        foreach (var s in queryLowNums3)
        {
            Console.Write(s.ToString() + " ");
        }
    }
}
// Output:
// 4 2 0
// 4 2 0

```

Example 3

A `where` clause may contain one or more methods that return Boolean values. In the following example, the `where` clause uses a method to determine whether the current value of the range variable is even or odd.

```

class WhereSample3
{
    static void Main()
    {
        // Data source
        int[] numbers = { 5, 4, 1, 3, 9, 8, 6, 7, 2, 0 };

        // Create the query with a method call in the where clause.
        // Note: This won't work in LINQ to SQL unless you have a
        // stored procedure that is mapped to a method by this name.
        var queryEvenNums =
            from num in numbers
            where IsEven(num)
            select num;

        // Execute the query.
        foreach (var s in queryEvenNums)
        {
            Console.Write(s.ToString() + " ");
        }

        // Method may be instance method or static method.
        static bool IsEven(int i)
        {
            return i % 2 == 0;
        }
    }
}
//Output: 4 8 6 2 0

```

Remarks

The `where` clause is a filtering mechanism. It can be positioned almost anywhere in a query expression, except it cannot be the first or last clause. A `where` clause may appear either before or after a `group` clause depending on whether you have to filter the source elements before or after they are grouped.

If a specified predicate is not valid for the elements in the data source, a compile-time error will result. This is one benefit of the strong type-checking provided by LINQ.

At compile time the `where` keyword is converted into a call to the [Where](#) Standard Query Operator method.

- [LINQ in C#](#)
- [Language Integrated Query \(LINQ\)](#)

select clause (C# Reference)

12/28/2021 • 6 minutes to read • [Edit Online](#)

In a query expression, the `select` clause specifies the type of values that will be produced when the query is executed. The result is based on the evaluation of all the previous clauses and on any expressions in the `select` clause itself. A query expression must terminate with either a `select` clause or a `group` clause.

The following example shows a simple `select` clause in a query expression.

```
class SelectSample1
{
    static void Main()
    {
        //Create the data source
        List<int> Scores = new List<int>() { 97, 92, 81, 60 };

        // Create the query.
        IEnumerable<int> queryHighScores =
            from score in Scores
            where score > 80
            select score;

        // Execute the query.
        foreach (int i in queryHighScores)
        {
            Console.Write(i + " ");
        }
    }
}
//Output: 97 92 81
```

The type of the sequence produced by the `select` clause determines the type of the query variable `queryHighScores`. In the simplest case, the `select` clause just specifies the range variable. This causes the returned sequence to contain elements of the same type as the data source. For more information, see [Type Relationships in LINQ Query Operations](#). However, the `select` clause also provides a powerful mechanism for transforming (or *projecting*) source data into new types. For more information, see [Data Transformations with LINQ \(C#\)](#).

Example

The following example shows all the different forms that a `select` clause may take. In each query, note the relationship between the `select` clause and the type of the *query variable* (`studentQuery1`, `studentQuery2`, and so on).

```
class SelectSample2
{
    // Define some classes
    public class Student
    {
        public string First { get; set; }
        public string Last { get; set; }
        public int ID { get; set; }
        public List<int> Scores;
        public ContactInfo GetContactInfo(SelectSample2 app, int id)
        {
            ContactInfo cInfo =
```

```

        (from ci in app.contactList
         where ci.ID == id
         select ci)
        .FirstOrDefault();

        return cInfo;
    }

    public override string ToString()
    {
        return First + " " + Last + ":" + ID;
    }
}

public class ContactInfo
{
    public int ID { get; set; }
    public string Email { get; set; }
    public string Phone { get; set; }
    public override string ToString() { return Email + "," + Phone; }
}

public class ScoreInfo
{
    public double Average { get; set; }
    public int ID { get; set; }
}

// The primary data source
List<Student> students = new List<Student>()
{
    new Student {First="Svetlana", Last="Omelchenko", ID=111, Scores= new List<int>() {97, 92, 81,
60}},
    new Student {First="Claire", Last="O'Donnell", ID=112, Scores= new List<int>() {75, 84, 91,
39}},
    new Student {First="Sven", Last="Mortensen", ID=113, Scores= new List<int>() {88, 94, 65, 91}},
    new Student {First="Cesar", Last="Garcia", ID=114, Scores= new List<int>() {97, 89, 85, 82}},
};

// Separate data source for contact info.
List<ContactInfo> contactList = new List<ContactInfo>()
{
    new ContactInfo {ID=111, Email="SvetlanO@Contoso.com", Phone="206-555-0108"},
    new ContactInfo {ID=112, Email="ClaireO@Contoso.com", Phone="206-555-0298"},
    new ContactInfo {ID=113, Email="SvenMort@Contoso.com", Phone="206-555-1130"},
    new ContactInfo {ID=114, Email="CesarGar@Contoso.com", Phone="206-555-0521"}
};

static void Main(string[] args)
{
    SelectSample2 app = new SelectSample2();

    // Produce a filtered sequence of unmodified Students.
    IEnumerable<Student> studentQuery1 =
        from student in app.students
        where student.ID > 111
        select student;

    Console.WriteLine("Query1: select range_variable");
    foreach (Student s in studentQuery1)
    {
        Console.WriteLine(s.ToString());
    }

    // Produce a filtered sequence of elements that contain
    // only one property of each Student.
    IEnumerable<String> studentQuery2 =
        from student in app.students
        where student.ID > 111

```

```

        select student.Last;

Console.WriteLine("\r\n studentQuery2: select range_variable.Property");
foreach (string s in studentQuery2)
{
    Console.WriteLine(s);
}

// Produce a filtered sequence of objects created by
// a method call on each Student.
IEnumerable<ContactInfo> studentQuery3 =
    from student in app.students
    where student.ID > 111
    select student.GetContactInfo(app, student.ID);

Console.WriteLine("\r\n studentQuery3: select range_variable.Method");
foreach (ContactInfo ci in studentQuery3)
{
    Console.WriteLine(ci.ToString());
}

// Produce a filtered sequence of ints from
// the internal array inside each Student.
IEnumerable<int> studentQuery4 =
    from student in app.students
    where student.ID > 111
    select student.Scores[0];

Console.WriteLine("\r\n studentQuery4: select range_variable[index]");
foreach (int i in studentQuery4)
{
    Console.WriteLine("First score = {0}", i);
}

// Produce a filtered sequence of doubles
// that are the result of an expression.
IEnumerable<double> studentQuery5 =
    from student in app.students
    where student.ID > 111
    select student.Scores[0] * 1.1;

Console.WriteLine("\r\n studentQuery5: select expression");
foreach (double d in studentQuery5)
{
    Console.WriteLine("Adjusted first score = {0}", d);
}

// Produce a filtered sequence of doubles that are
// the result of a method call.
IEnumerable<double> studentQuery6 =
    from student in app.students
    where student.ID > 111
    select student.Scores.Average();

Console.WriteLine("\r\n studentQuery6: select expression2");
foreach (double d in studentQuery6)
{
    Console.WriteLine("Average = {0}", d);
}

// Produce a filtered sequence of anonymous types
// that contain only two properties from each Student.
var studentQuery7 =
    from student in app.students
    where student.ID > 111
    select new { student.First, student.Last };

Console.WriteLine("\r\n studentQuery7: select new anonymous type");
foreach (var item in studentQuery7)

```

```

    {
        Console.WriteLine("{0}, {1}", item.Last, item.First);
    }

    // Produce a filtered sequence of named objects that contain
    // a method return value and a property from each Student.
    // Use named types if you need to pass the query variable
    // across a method boundary.
    IEnumerable<ScoreInfo> studentQuery8 =
        from student in app.students
        where student.ID > 111
        select new ScoreInfo
        {
            Average = student.Scores.Average(),
            ID = student.ID
        };

    Console.WriteLine("\r\n studentQuery8: select new named type");
    foreach (ScoreInfo si in studentQuery8)
    {
        Console.WriteLine("ID = {0}, Average = {1}", si.ID, si.Average);
    }

    // Produce a filtered sequence of students who appear on a contact list
    // and whose average is greater than 85.
    IEnumerable<ContactInfo> studentQuery9 =
        from student in app.students
        where student.Scores.Average() > 85
        join ci in app.contactList on student.ID equals ci.ID
        select ci;

    Console.WriteLine("\r\n studentQuery9: select result of join clause");
    foreach (ContactInfo ci in studentQuery9)
    {
        Console.WriteLine("ID = {0}, Email = {1}", ci.ID, ci.Email);
    }

    // Keep the console window open in debug mode
    Console.WriteLine("Press any key to exit.");
    Console.ReadKey();
}
}

ID = 114, Email = CesarGar@Contoso.com
*/

```

As shown in `studentQuery8` in the previous example, sometimes you might want the elements of the returned sequence to contain only a subset of the properties of the source elements. By keeping the returned sequence as small as possible you can reduce the memory requirements and increase the speed of the execution of the query. You can accomplish this by creating an anonymous type in the `select` clause and using an object initializer to initialize it with the appropriate properties from the source element. For an example of how to do this, see [Object and Collection Initializers](#).

Remarks

At compile time, the `select` clause is translated to a method call to the [Select](#) standard query operator.

group clause (C# Reference)

12/28/2021 • 8 minutes to read • [Edit Online](#)

The `group` clause returns a sequence of `IGrouping<TKey,TElement>` objects that contain zero or more items that match the key value for the group. For example, you can group a sequence of strings according to the first letter in each string. In this case, the first letter is the key and has a type `char`, and is stored in the `Key` property of each `IGrouping<TKey,TElement>` object. The compiler infers the type of the key.

You can end a query expression with a `group` clause, as shown in the following example:

```
// Query variable is an IEnumerable<IGrouping<char, Student>>
var studentQuery1 =
    from student in students
    group student by student.Last[0];
```

If you want to perform additional query operations on each group, you can specify a temporary identifier by using the `into` contextual keyword. When you use `into`, you must continue with the query, and eventually end it with either a `select` statement or another `group` clause, as shown in the following excerpt:

```
// Group students by the first letter of their last name
// Query variable is an IEnumerable<IGrouping<char, Student>>
var studentQuery2 =
    from student in students
    group student by student.Last[0] into g
    orderby g.Key
    select g;
```

More complete examples of the use of `group` with and without `into` are provided in the Example section of this article.

Enumerating the results of a group query

Because the `IGrouping<TKey,TElement>` objects produced by a `group` query are essentially a list of lists, you must use a nested `foreach` loop to access the items in each group. The outer loop iterates over the group keys, and the inner loop iterates over each item in the group itself. A group may have a key but no elements. The following is the `foreach` loop that executes the query in the previous code examples:

```
// Iterate group items with a nested foreach. This IGrouping encapsulates
// a sequence of Student objects, and a Key of type char.
// For convenience, var can also be used in the foreach statement.
foreach (IGrouping<char, Student> studentGroup in studentQuery2)
{
    Console.WriteLine(studentGroup.Key);
    // Explicit type for student could also be used here.
    foreach (var student in studentGroup)
    {
        Console.WriteLine("  {0}, {1}", student.Last, student.First);
    }
}
```

Key types

Group keys can be any type, such as a string, a built-in numeric type, or a user-defined named type or anonymous type.

Grouping by string

The previous code examples used a `char`. A string key could easily have been specified instead, for example the complete last name:

```
// Same as previous example except we use the entire last name as a key.  
// Query variable is an IEnumerable<IGrouping<string, Student>>  
var studentQuery3 =  
    from student in students  
    group student by student.Last;
```

Grouping by bool

The following example shows the use of a bool value for a key to divide the results into two groups. Note that the value is produced by a sub-expression in the `group` clause.

```

class GroupSample1
{
    // The element type of the data source.
    public class Student
    {
        public string First { get; set; }
        public string Last { get; set; }
        public int ID { get; set; }
        public List<int> Scores;
    }

    public static List<Student> GetStudents()
    {
        // Use a collection initializer to create the data source. Note that each element
        // in the list contains an inner sequence of scores.
        List<Student> students = new List<Student>
        {
            new Student {First="Svetlana", Last="Omelchenko", ID=111, Scores= new List<int> {97, 72, 81,
60}},
            new Student {First="Claire", Last="O'Donnell", ID=112, Scores= new List<int> {75, 84, 91, 39}},
            new Student {First="Sven", Last="Mortensen", ID=113, Scores= new List<int> {99, 89, 91, 95}},
            new Student {First="Cesar", Last="Garcia", ID=114, Scores= new List<int> {72, 81, 65, 84}},
            new Student {First="Debra", Last="Garcia", ID=115, Scores= new List<int> {97, 89, 85, 82}}
        };

        return students;
    }

    static void Main()
    {
        // Obtain the data source.
        List<Student> students = GetStudents();

        // Group by true or false.
        // Query variable is an IEnumerable<IGrouping<bool, Student>>
        var booleanGroupQuery =
            from student in students
            group student by student.Scores.Average() >= 80; //pass or fail!

        // Execute the query and access items in each group
        foreach (var studentGroup in booleanGroupQuery)
        {
            Console.WriteLine(studentGroup.Key == true ? "High averages" : "Low averages");
            foreach (var student in studentGroup)
            {
                Console.WriteLine("    {0}, {1}:{2}", student.Last, student.First, student.Scores.Average());
            }
        }

        // Keep the console window open in debug mode.
        Console.WriteLine("Press any key to exit.");
        Console.ReadKey();
    }
}
/* Output:
Low averages
Omelchenko, Svetlana:77.5
O'Donnell, Claire:72.25
Garcia, Cesar:75.5
High averages
Mortensen, Sven:93.5
Garcia, Debra:88.25
*/

```

Grouping by numeric range

The next example uses an expression to create numeric group keys that represent a percentile range. Note the

use of [let](#) as a convenient location to store a method call result, so that you don't have to call the method two times in the `group` clause. For more information about how to safely use methods in query expressions, see [Handle exceptions in query expressions](#).

```
class GroupSample2
{
    // The element type of the data source.
    public class Student
    {
        public string First { get; set; }
        public string Last { get; set; }
        public int ID { get; set; }
        public List<int> Scores;
    }

    public static List<Student> GetStudents()
    {
        // Use a collection initializer to create the data source. Note that each element
        // in the list contains an inner sequence of scores.
        List<Student> students = new List<Student>
        {
            new Student {First="Svetlana", Last="Omelchenko", ID=111, Scores= new List<int> {97, 72, 81,
60}},
            new Student {First="Claire", Last="O'Donnell", ID=112, Scores= new List<int> {75, 84, 91, 39}},
            new Student {First="Sven", Last="Mortensen", ID=113, Scores= new List<int> {99, 89, 91, 95}},
            new Student {First="Cesar", Last="Garcia", ID=114, Scores= new List<int> {72, 81, 65, 84}},
            new Student {First="Debra", Last="Garcia", ID=115, Scores= new List<int> {97, 89, 85, 82}}
        };

        return students;
    }

    // This method groups students into percentile ranges based on their
    // grade average. The Average method returns a double, so to produce a whole
    // number it is necessary to cast to int before dividing by 10.
    static void Main()
    {
        // Obtain the data source.
        List<Student> students = GetStudents();

        // Write the query.
        var studentQuery =
            from student in students
            let avg = (int)student.Scores.Average()
            group student by (avg / 10) into g
            orderby g.Key
            select g;

        // Execute the query.
        foreach (var studentGroup in studentQuery)
        {
            int temp = studentGroup.Key * 10;
            Console.WriteLine("Students with an average between {0} and {1}", temp, temp + 10);
            foreach (var student in studentGroup)
            {
                Console.WriteLine("    {0}, {1}:{2}", student.Last, student.First, student.Scores.Average());
            }
        }

        // Keep the console window open in debug mode.
        Console.WriteLine("Press any key to exit.");
        Console.ReadKey();
    }
}

/* Output:
    Students with an average between 70 and 80
    Omelchenko, Svetlana:77.5
```

```
O'Donnell, Claire:72.25
Garcia, Cesar:75.5
Students with an average between 80 and 90
Garcia, Debra:88.25
Students with an average between 90 and 100
Mortensen, Sven:93.5

*/
```

Grouping by composite keys

Use a composite key when you want to group elements according to more than one key. You create a composite key by using an anonymous type or a named type to hold the key element. In the following example, assume that a class `Person` has been declared with members named `surname` and `city`. The `group` clause causes a separate group to be created for each set of persons with the same last name and the same city.

```
group person by new {name = person.surname, city = person.city};
```

Use a named type if you must pass the query variable to another method. Create a special class using auto-implemented properties for the keys, and then override the [Equals](#) and [GetHashCode](#) methods. You can also use a struct, in which case you do not strictly have to override those methods. For more information see [How to implement a lightweight class with auto-implemented properties](#) and [How to query for duplicate files in a directory tree](#). The latter article has a code example that demonstrates how to use a composite key with a named type.

Example 1

The following example shows the standard pattern for ordering source data into groups when no additional query logic is applied to the groups. This is called a grouping without a continuation. The elements in an array of strings are grouped according to their first letter. The result of the query is an `IGrouping<TKey,TElement>` type that contains a public `Key` property of type `char` and an `IEnumerable<T>` collection that contains each item in the grouping.

The result of a `group` clause is a sequence of sequences. Therefore, to access the individual elements within each returned group, use a nested `foreach` loop inside the loop that iterates the group keys, as shown in the following example.

```

class GroupExample1
{
    static void Main()
    {
        // Create a data source.
        string[] words = { "blueberry", "chimpanzee", "abacus", "banana", "apple", "cheese" };

        // Create the query.
        var wordGroups =
            from w in words
            group w by w[0];

        // Execute the query.
        foreach (var wordGroup in wordGroups)
        {
            Console.WriteLine("Words that start with the letter '{0}':", wordGroup.Key);
            foreach (var word in wordGroup)
            {
                Console.WriteLine(word);
            }
        }

        // Keep the console window open in debug mode
        Console.WriteLine("Press any key to exit.");
        Console.ReadKey();
    }
}
/* Output:
Words that start with the letter 'b':
blueberry
banana
Words that start with the letter 'c':
chimpanzee
cheese
Words that start with the letter 'a':
abacus
apple
*/

```

Example 2

This example shows how to perform additional logic on the groups after you have created them, by using a *continuation* with `into`. For more information, see [into](#). The following example queries each group to select only those whose key value is a vowel.

```

class GroupClauseExample2
{
    static void Main()
    {
        // Create the data source.
        string[] words2 = { "blueberry", "chimpanzee", "abacus", "banana", "apple", "cheese", "elephant",
"umbrella", "anteater" };

        // Create the query.
        var wordGroups2 =
            from w in words2
            group w by w[0] into grps
            where (grps.Key == 'a' || grps.Key == 'e' || grps.Key == 'i'
                || grps.Key == 'o' || grps.Key == 'u')
            select grps;

        // Execute the query.
        foreach (var wordGroup in wordGroups2)
        {
            Console.WriteLine("Groups that start with a vowel: {0}", wordGroup.Key);
            foreach (var word in wordGroup)
            {
                Console.WriteLine("    {0}", word);
            }
        }

        // Keep the console window open in debug mode
        Console.WriteLine("Press any key to exit.");
        Console.ReadKey();
    }
}
/* Output:
    Groups that start with a vowel: a
        abacus
        apple
        anteater
    Groups that start with a vowel: e
        elephant
    Groups that start with a vowel: u
        umbrella
*/

```

Remarks

At compile time, `group` clauses are translated into calls to the [GroupBy](#) method.

into (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `into` contextual keyword can be used to create a temporary identifier to store the results of a [group](#), [join](#) or [select](#) clause into a new identifier. This identifier can itself be a generator for additional query commands. When used in a `group` or `select` clause, the use of the new identifier is sometimes referred to as a *continuation*.

Example

The following example shows the use of the `into` keyword to enable a temporary identifier `fruitGroup` which has an inferred type of `IGrouping`. By using the identifier, you can invoke the [Count](#) method on each group and select only those groups that contain two or more words.

```
class IntoSample1
{
    static void Main()
    {
        // Create a data source.
        string[] words = { "apples", "blueberries", "oranges", "bananas", "apricots"};

        // Create the query.
        var wordGroups1 =
            from w in words
            group w by w[0] into fruitGroup
            where fruitGroup.Count() >= 2
            select new { FirstLetter = fruitGroup.Key, Words = fruitGroup.Count() };

        // Execute the query. Note that we only iterate over the groups,
        // not the items in each group
        foreach (var item in wordGroups1)
        {
            Console.WriteLine(" {0} has {1} elements.", item.FirstLetter, item.Words);
        }

        // Keep the console window open in debug mode
        Console.WriteLine("Press any key to exit.");
        Console.ReadKey();
    }
}
/* Output:
a has 2 elements.
b has 2 elements.
*/
```

The use of `into` in a `group` clause is only necessary when you want to perform additional query operations on each group. For more information, see [group clause](#).

For an example of the use of `into` in a `join` clause, see [join clause](#).

See also

- [Query Keywords \(LINQ\)](#)
- [LINQ in C#](#)
- [group clause](#)

orderby clause (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

In a query expression, the `orderby` clause causes the returned sequence or subsequence (group) to be sorted in either ascending or descending order. Multiple keys can be specified in order to perform one or more secondary sort operations. The sorting is performed by the default comparer for the type of the element. The default sort order is ascending. You can also specify a custom comparer. However, it is only available by using method-based syntax. For more information, see [Sorting Data](#).

Example 1

In the following example, the first query sorts the words in alphabetical order starting from A, and second query sorts the same words in descending order. (The `ascending` keyword is the default sort value and can be omitted.)

```

class OrderbySample1
{
    static void Main()
    {
        // Create a delicious data source.
        string[] fruits = { "cherry", "apple", "blueberry" };

        // Query for ascending sort.
        IEnumerable<string> sortAscendingQuery =
            from fruit in fruits
            orderby fruit //"ascending" is default
            select fruit;

        // Query for descending sort.
        IEnumerable<string> sortDescendingQuery =
            from w in fruits
            orderby w descending
            select w;

        // Execute the query.
        Console.WriteLine("Ascending:");
        foreach (string s in sortAscendingQuery)
        {
            Console.WriteLine(s);
        }

        // Execute the query.
        Console.WriteLine(Environment.NewLine + "Descending:");
        foreach (string s in sortDescendingQuery)
        {
            Console.WriteLine(s);
        }

        // Keep the console window open in debug mode.
        Console.WriteLine("Press any key to exit.");
        Console.ReadKey();
    }
}
/* Output:
Ascending:
apple
blueberry
cherry

Descending:
cherry
blueberry
apple
*/

```

Example 2

The following example performs a primary sort on the students' last names, and then a secondary sort on their first names.

```

class OrderbySample2
{
    // The element type of the data source.
    public class Student
    {
        public string First { get; set; }
        public string Last { get; set; }
        public int ID { get; set; }
    }
}

```

```

public static List<Student> GetStudents()
{
    // Use a collection initializer to create the data source. Note that each element
    // in the list contains an inner sequence of scores.
    List<Student> students = new List<Student>
    {
        new Student {First="Svetlana", Last="Omelchenko", ID=111},
        new Student {First="Claire", Last="O'Donnell", ID=112},
        new Student {First="Sven", Last="Mortensen", ID=113},
        new Student {First="Cesar", Last="Garcia", ID=114},
        new Student {First="Debra", Last="Garcia", ID=115}
    };

    return students;
}
static void Main(string[] args)
{
    // Create the data source.
    List<Student> students = GetStudents();

    // Create the query.
    IEnumerable<Student> sortedStudents =
        from student in students
        orderby student.Last ascending, student.First ascending
        select student;

    // Execute the query.
    Console.WriteLine("sortedStudents:");
    foreach (Student student in sortedStudents)
        Console.WriteLine(student.Last + " " + student.First);

    // Now create groups and sort the groups. The query first sorts the names
    // of all students so that they will be in alphabetical order after they are
    // grouped. The second orderby sorts the group keys in alpha order.
    var sortedGroups =
        from student in students
        orderby student.Last, student.First
        group student by student.Last[0] into newGroup
        orderby newGroup.Key
        select newGroup;

    // Execute the query.
    Console.WriteLine(Environment.NewLine + "sortedGroups:");
    foreach (var studentGroup in sortedGroups)
    {
        Console.WriteLine(studentGroup.Key);
        foreach (var student in studentGroup)
        {
            Console.WriteLine("    {0}, {1}", student.Last, student.First);
        }
    }

    // Keep the console window open in debug mode
    Console.WriteLine("Press any key to exit.");
    Console.ReadKey();
}
}
/* Output:
sortedStudents:
Garcia Cesar
Garcia Debra
Mortensen Sven
O'Donnell Claire
Omelchenko Svetlana

sortedGroups:
G
    Garcia, Cesar
    Garcia, Debra

```

```
Garcia, Debra
M
Mortensen, Sven
O
O'Donnell, Claire
Omelchenko, Svetlana
*/
```

Remarks

At compile time, the `orderby` clause is translated to a call to the [OrderBy](#) method. Multiple keys in the `orderby` clause translate to [ThenBy](#) method calls.

join clause (C# Reference)

12/28/2021 • 10 minutes to read • [Edit Online](#)

The `join` clause is useful for associating elements from different source sequences that have no direct relationship in the object model. The only requirement is that the elements in each source share some value that can be compared for equality. For example, a food distributor might have a list of suppliers of a certain product, and a list of buyers. A `join` clause can be used, for example, to create a list of the suppliers and buyers of that product who are all in the same specified region.

A `join` clause takes two source sequences as input. The elements in each sequence must either be or contain a property that can be compared to a corresponding property in the other sequence. The `join` clause compares the specified keys for equality by using the special `equals` keyword. All joins performed by the `join` clause are equijoins. The shape of the output of a `join` clause depends on the specific type of join you are performing. The following are three most common join types:

- Inner join
- Group join
- Left outer join

Inner join

The following example shows a simple inner equijoin. This query produces a flat sequence of "product name / category" pairs. The same category string will appear in multiple elements. If an element from `categories` has no matching `products`, that category will not appear in the results.

```
var innerJoinQuery =  
    from category in categories  
    join prod in products on category.ID equals prod.CategoryID  
    select new { ProductName = prod.Name, Category = category.Name }; //produces flat sequence
```

For more information, see [Perform inner joins](#).

Group join

A `join` clause with an `into` expression is called a group join.

```
var innerGroupJoinQuery =  
    from category in categories  
    join prod in products on category.ID equals prod.CategoryID into prodGroup  
    select new { CategoryName = category.Name, Products = prodGroup };
```

A group join produces a hierarchical result sequence, which associates elements in the left source sequence with one or more matching elements in the right side source sequence. A group join has no equivalent in relational terms; it is essentially a sequence of object arrays.

If no elements from the right source sequence are found to match an element in the left source, the `join` clause will produce an empty array for that item. Therefore, the group join is still basically an inner-equijoin except that the result sequence is organized into groups.

If you just select the results of a group join, you can access the items, but you cannot identify the key that they

match on. Therefore, it is generally more useful to select the results of the group join into a new type that also has the key name, as shown in the previous example.

You can also, of course, use the result of a group join as the generator of another subquery:

```
var innerGroupJoinQuery2 =  
    from category in categories  
    join prod in products on category.ID equals prod.CategoryID into prodGroup  
    from prod2 in prodGroup  
    where prod2.UnitPrice > 2.50M  
    select prod2;
```

For more information, see [Perform grouped joins](#).

Left outer join

In a left outer join, all the elements in the left source sequence are returned, even if no matching elements are in the right sequence. To perform a left outer join in LINQ, use the `DefaultIfEmpty` method in combination with a group join to specify a default right-side element to produce if a left-side element has no matches. You can use `null` as the default value for any reference type, or you can specify a user-defined default type. In the following example, a user-defined default type is shown:

```
var leftOuterJoinQuery =  
    from category in categories  
    join prod in products on category.ID equals prod.CategoryID into prodGroup  
    from item in prodGroup.DefaultIfEmpty(new Product { Name = String.Empty, CategoryID = 0 })  
    select new { CatName = category.Name, ProdName = item.Name };
```

For more information, see [Perform left outer joins](#).

The equals operator

A `join` clause performs an equijoin. In other words, you can only base matches on the equality of two keys. Other types of comparisons such as "greater than" or "not equals" are not supported. To make clear that all joins are equijoins, the `join` clause uses the `equals` keyword instead of the `==` operator. The `equals` keyword can only be used in a `join` clause and it differs from the `==` operator in some important ways. When comparing strings, `equals` has an overload to compare by value and the operator `==` uses reference equality. When both sides of comparison have identical string variables, `equals` and `==` will reach the same result: true. That's because, when a program declares two or more equivalent string variables, the compiler stores all of them in the same location, see [Reference equality and string interning](#) for more information. Another important difference is the null comparison: `null equals null` is evaluated as false with `equals` operator, instead of `==` operator that evaluates it as true. Lastly, the scoping behavior is different: with `equals`, the left key consumes the outer source sequence, and the right key consumes the inner source. The outer source is only in scope on the left side of `equals` and the inner source sequence is only in scope on the right side.

Non-equijoins

You can perform non-equijoins, cross joins, and other custom join operations by using multiple `from` clauses to introduce new sequences independently into a query. For more information, see [Perform custom join operations](#).

Joins on object collections vs. relational tables

In a LINQ query expression, join operations are performed on object collections. Object collections cannot be

"joined" in exactly the same way as two relational tables. In LINQ, explicit `join` clauses are only required when two source sequences are not tied by any relationship. When working with LINQ to SQL, foreign key tables are represented in the object model as properties of the primary table. For example, in the Northwind database, the Customer table has a foreign key relationship with the Orders table. When you map the tables to the object model, the Customer class has an Orders property that contains the collection of Orders associated with that Customer. In effect, the join has already been done for you.

For more information about querying across related tables in the context of LINQ to SQL, see [How to: Map Database Relationships](#).

Composite keys

You can test for equality of multiple values by using a composite key. For more information, see [Join by using composite keys](#). Composite keys can be also used in a `group` clause.

Example

The following example compares the results of an inner join, a group join, and a left outer join on the same data sources by using the same matching keys. Some extra code is added to these examples to clarify the results in the console display.

```
class JoinDemonstration
{
    #region Data

    class Product
    {
        public string Name { get; set; }
        public int CategoryID { get; set; }
    }

    class Category
    {
        public string Name { get; set; }
        public int ID { get; set; }
    }

    // Specify the first data source.
    List<Category> categories = new List<Category>()
    {
        new Category {Name="Beverages", ID=001},
        new Category {Name="Condiments", ID=002},
        new Category {Name="Vegetables", ID=003},
        new Category {Name="Grains", ID=004},
        new Category {Name="Fruit", ID=005}
    };

    // Specify the second data source.
    List<Product> products = new List<Product>()
    {
        new Product {Name="Cola", CategoryID=001},
        new Product {Name="Tea", CategoryID=001},
        new Product {Name="Mustard", CategoryID=002},
        new Product {Name="Pickles", CategoryID=002},
        new Product {Name="Carrots", CategoryID=003},
        new Product {Name="Bok Choy", CategoryID=003},
        new Product {Name="Peaches", CategoryID=005},
        new Product {Name="Melons", CategoryID=005},
    };
    #endregion

    static void Main(string[] args)
    {

```

```

let clause (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

In a query expression, it is sometimes useful to store the result of a sub-expression in order to use it in subsequent clauses. You can do this with the `let` keyword, which creates a new range variable and initializes it with the result of the expression you supply. Once initialized with a value, the range variable cannot be used to store another value. However, if the range variable holds a queryable type, it can be queried.

Example

In the following example `let` is used in two ways:

1. To create an enumerable type that can itself be queried.
2. To enable the query to call `ToLower` only one time on the range variable `word`. Without using `let`, you would have to call `ToLower` in each predicate in the `where` clause.

```

class LetSample1
{
    static void Main()
    {
        string[] strings =
        {
            "A penny saved is a penny earned.",
            "The early bird catches the worm.",
            "The pen is mightier than the sword."
        };

        // Split the sentence into an array of words
        // and select those whose first letter is a vowel.
        var earlyBirdQuery =
            from sentence in strings
            let words = sentence.Split(' ')
            from word in words
            let w = word.ToLower()
            where w[0] == 'a' || w[0] == 'e'
                || w[0] == 'i' || w[0] == 'o'
                || w[0] == 'u'
            select word;

        // Execute the query.
        foreach (var v in earlyBirdQuery)
        {
            Console.WriteLine("{0}" starts with a vowel", v);
        }

        // Keep the console window open in debug mode.
        Console.WriteLine("Press any key to exit.");
        Console.ReadKey();
    }
}
/* Output:
    "A" starts with a vowel
    "is" starts with a vowel
    "a" starts with a vowel
    "earned." starts with a vowel
    "early" starts with a vowel
    "is" starts with a vowel
*/

ascending (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `ascending` contextual keyword is used in the [orderby clause](#) in query expressions to specify that the sort order is from smallest to largest. Because `ascending` is the default sort order, you do not have to specify it.

Example

The following example shows the use of `ascending` in an [orderby clause](#).

```
IEnumerable<string> sortAscendingQuery =  
    from vegetable in vegetables  
    orderby vegetable ascending  
    select vegetable;
```

C# operators and expressions (C# reference)

12/28/2021 • 5 minutes to read • [Edit Online](#)

C# provides a number of operators. Many of them are supported by the [built-in types](#) and allow you to perform basic operations with values of those types. Those operators include the following groups:

- [Arithmetic operators](#) that perform arithmetic operations with numeric operands
- [Comparison operators](#) that compare numeric operands
- [Boolean logical operators](#) that perform logical operations with `bool` operands
- [Bitwise and shift operators](#) that perform bitwise or shift operations with operands of the integral types
- [Equality operators](#) that check if their operands are equal or not

Typically, you can [overload](#) those operators, that is, specify the operator behavior for the operands of a user-defined type.

The simplest C# expressions are literals (for example, [integer](#) and [real](#) numbers) and names of variables. You can combine them into complex expressions by using operators. Operator [precedence](#) and [associativity](#) determine the order in which the operations in an expression are performed. You can use parentheses to change the order of evaluation imposed by operator precedence and associativity.

In the following code, examples of expressions are at the right-hand side of assignments:

```
int a, b, c;
a = 7;
b = a;
c = b++;
b = a + b * c;
c = a >= 100 ? b : c / 10;
a = (int)Math.Sqrt(b * b + c * c);

string s = "String literal";
char l = s[s.Length - 1];

var numbers = new List<int>(new[] { 1, 2, 3 });
b = numbers.FindLast(n => n > 1);
```

Typically, an expression produces a result and can be included in another expression. A `void` method call is an example of an expression that doesn't produce a result. It can be used only as a [statement](#), as the following example shows:

```
Console.WriteLine("Hello, world!");
```

Here are some other kinds of expressions that C# provides:

- [Interpolated string expressions](#) that provide convenient syntax to create formatted strings:

```
var r = 2.3;
var message = $"The area of a circle with radius {r} is {Math.PI * r * r:F3}.";
Console.WriteLine(message);
// Output:
// The area of a circle with radius 2.3 is 16.619.
```

- [Lambda expressions](#) that allow you to create anonymous functions:

```
int[] numbers = { 2, 3, 4, 5 };
var maximumSquare = numbers.Max(x => x * x);
Console.WriteLine(maximumSquare);
// Output:
// 25
```

- [Query expressions](#) that allow you to use query capabilities directly in C#:

```
var scores = new[] { 90, 97, 78, 68, 85 };
IEnumerable<int> highScoresQuery =
    from score in scores
    where score > 80
    orderby score descending
    select score;
Console.WriteLine(string.Join(" ", highScoresQuery));
// Output:
// 97 90 85
```

You can use an [expression body definition](#) to provide a concise definition for a method, constructor, property, indexer, or finalizer.

Operator precedence

In an expression with multiple operators, the operators with higher precedence are evaluated before the operators with lower precedence. In the following example, the multiplication is performed first because it has higher precedence than addition:

```
var a = 2 + 2 * 2;
Console.WriteLine(a); // output: 6
```

Use parentheses to change the order of evaluation imposed by operator precedence:

```
var a = (2 + 2) * 2;
Console.WriteLine(a); // output: 8
```

The following table lists the C# operators starting with the highest precedence to the lowest. The operators within each row have the same precedence.

OPERATORS	CATEGORY OR NAME
<code>x.y</code> , <code>f(x)</code> , <code>a[i]</code> , <code>x?.y</code> , <code>x?[y]</code> , <code>x++</code> , <code>x--</code> , <code>x!</code> , <code>new</code> , <code>typeof</code> , <code>checked</code> , <code>unchecked</code> , <code>default</code> , <code>nameof</code> , <code>delegate</code> , <code>sizeof</code> , <code>stackalloc</code> , <code>x->y</code>	Primary
<code>+x</code> , <code>-x</code> , <code>!x</code> , <code>~x</code> , <code>++x</code> , <code>--x</code> , <code>^x</code> , <code>(T)x</code> , <code>await</code> , <code>&x</code> , <code>*x</code> , <code>true</code> and <code>false</code>	Unary
<code>x..y</code>	Range
<code>switch</code> , <code>with</code>	<code>switch</code> and <code>with</code> expressions
<code>x * y</code> , <code>x / y</code> , <code>x % y</code>	Multiplicative
<code>x + y</code> , <code>x - y</code>	Additive

OPERATORS	CATEGORY OR NAME
<code>x << y, x >> y</code>	Shift
<code>x < y, x > y, x <= y, x >= y, is, as</code>	Relational and type-testing
<code>x == y, x != y</code>	Equality
<code>x & y</code>	Boolean logical AND or bitwise logical AND
<code>x ^ y</code>	Boolean logical XOR or bitwise logical XOR
<code>x y</code>	Boolean logical OR or bitwise logical OR
<code>x && y</code>	Conditional AND
<code>x y</code>	Conditional OR
<code>x ?? y</code>	Null-coalescing operator
<code>c ? t : f</code>	Conditional operator
<code>x = y, x += y, x -= y, x *= y, x /= y, x %= y, x &= y, x = y, x ^= y, x <<= y, x >>= y, x ??= y, =></code>	Assignment and lambda declaration

Operator associativity

When operators have the same precedence, associativity of the operators determines the order in which the operations are performed:

- *Left-associative* operators are evaluated in order from left to right. Except for the [assignment operators](#) and the [null-coalescing operators](#), all binary operators are left-associative. For example, `a + b - c` is evaluated as `(a + b) - c`.
- *Right-associative* operators are evaluated in order from right to left. The assignment operators, the null-coalescing operators, and the [conditional operator](#) `?:` are right-associative. For example, `x = y = z` is evaluated as `x = (y = z)`.

Use parentheses to change the order of evaluation imposed by operator associativity:

```
int a = 13 / 5 / 2;
int b = 13 / (5 / 2);
Console.WriteLine($"a = {a}, b = {b}"); // output: a = 1, b = 6
```

Operand evaluation

Unrelated to operator precedence and associativity, operands in an expression are evaluated from left to right. The following examples demonstrate the order in which operators and operands are evaluated:

EXPRESSION	ORDER OF EVALUATION
<code>a + b</code>	a, b, +

EXPRESSION	ORDER OF EVALUATION
<code>a + b * c</code>	a, b, c, *, +
<code>a / b + c * d</code>	a, b, /, c, d, *, +
<code>a / (b + c) * d</code>	a, b, c, +, /, d, *

Typically, all operator operands are evaluated. However, some operators evaluate operands conditionally. That is, the value of the leftmost operand of such an operator defines if (or which) other operands should be evaluated. These operators are the conditional logical [AND](#) (`&&`) and [OR](#) (`||`) operators, the [null-coalescing operators](#) `??` and `??=`, the [null-conditional operators](#) `?.` and `?[]`, and the [conditional operator](#) `?:`. For more information, see the description of each operator.

C# language specification

For more information, see the following sections of the [C# language specification](#):

- [Expressions](#)
- [Operators](#)

- [Expression trees](#)

Arithmetic operators (C# reference)

12/28/2021 • 9 minutes to read • [Edit Online](#)

The following operators perform arithmetic operations with operands of numeric types:

- Unary `++` (increment), `--` (decrement), `+` (plus), and `-` (minus) operators
- Binary `*` (multiplication), `/` (division), `%` (remainder), `+` (addition), and `-` (subtraction) operators

Those operators are supported by all [integral](#) and [floating-point](#) numeric types.

In the case of integral types, those operators (except the `++` and `--` operators) are defined for the `int`, `uint`, `long`, and `ulong` types. When operands are of other integral types (`sbyte`, `byte`, `short`, `ushort`, or `char`), their values are converted to the `int` type, which is also the result type of an operation. When operands are of different integral or floating-point types, their values are converted to the closest containing type, if such a type exists. For more information, see the [Numeric promotions](#) section of the [C# language specification](#). The `++` and `--` operators are defined for all integral and floating-point numeric types and the `char` type.

Increment operator ++

The unary increment operator `++` increments its operand by 1. The operand must be a variable, a [property](#) access, or an [indexer](#) access.

The increment operator is supported in two forms: the postfix increment operator, `x++`, and the prefix increment operator, `++x`.

Postfix increment operator

The result of `x++` is the value of `x` *before* the operation, as the following example shows:

```
int i = 3;
Console.WriteLine(i); // output: 3
Console.WriteLine(i++); // output: 3
Console.WriteLine(i); // output: 4
```

Prefix increment operator

The result of `++x` is the value of `x` *after* the operation, as the following example shows:

```
double a = 1.5;
Console.WriteLine(a); // output: 1.5
Console.WriteLine(++a); // output: 2.5
Console.WriteLine(a); // output: 2.5
```

Decrement operator --

The unary decrement operator `--` decrements its operand by 1. The operand must be a variable, a [property](#) access, or an [indexer](#) access.

The decrement operator is supported in two forms: the postfix decrement operator, `x--`, and the prefix decrement operator, `--x`.

Postfix decrement operator

The result of `x--` is the value of `x` *before* the operation, as the following example shows:

```
int i = 3;
Console.WriteLine(i);    // output: 3
Console.WriteLine(i--); // output: 3
Console.WriteLine(i);    // output: 2
```

Prefix decrement operator

The result of `--x` is the value of `x` *after* the operation, as the following example shows:

```
double a = 1.5;
Console.WriteLine(a);    // output: 1.5
Console.WriteLine(--a);  // output: 0.5
Console.WriteLine(a);    // output: 0.5
```

Unary plus and minus operators

The unary `+` operator returns the value of its operand. The unary `-` operator computes the numeric negation of its operand.

```
Console.WriteLine(+4);    // output: 4

Console.WriteLine(-4);    // output: -4
Console.WriteLine(-(-4)); // output: 4

uint a = 5;
var b = -a;
Console.WriteLine(b);      // output: -5
Console.WriteLine(b.GetType()); // output: System.Int64

Console.WriteLine(-double.NaN); // output: NaN
```

The `ulong` type doesn't support the unary `-` operator.

Multiplication operator *

The multiplication operator `*` computes the product of its operands:

```
Console.WriteLine(5 * 2);    // output: 10
Console.WriteLine(0.5 * 2.5); // output: 1.25
Console.WriteLine(0.1m * 23.4m); // output: 2.34
```

The unary `*` operator is the [pointer indirection operator](#).

Division operator /

The division operator `/` divides its left-hand operand by its right-hand operand.

Integer division

For the operands of integer types, the result of the `/` operator is of an integer type and equals the quotient of the two operands rounded towards zero:

```
Console.WriteLine(13 / 5);    // output: 2
Console.WriteLine(-13 / 5);   // output: -2
Console.WriteLine(13 / -5);   // output: -2
Console.WriteLine(-13 / -5);  // output: 2
```

To obtain the quotient of the two operands as a floating-point number, use the `float`, `double`, or `decimal` type:

```
Console.WriteLine(13 / 5.0);    // output: 2.6

int a = 13;
int b = 5;
Console.WriteLine((double)a / b); // output: 2.6
```

Floating-point division

For the `float`, `double`, and `decimal` types, the result of the `/` operator is the quotient of the two operands:

```
Console.WriteLine(16.8f / 4.1f); // output: 4.097561
Console.WriteLine(16.8d / 4.1d); // output: 4.09756097560976
Console.WriteLine(16.8m / 4.1m); // output: 4.0975609756097560975609756098
```

If one of the operands is `decimal`, another operand can be neither `float` nor `double`, because neither `float` nor `double` is implicitly convertible to `decimal`. You must explicitly convert the `float` or `double` operand to the `decimal` type. For more information about conversions between numeric types, see [Built-in numeric conversions](#).

Remainder operator %

The remainder operator `%` computes the remainder after dividing its left-hand operand by its right-hand operand.

Integer remainder

For the operands of integer types, the result of `a % b` is the value produced by `a - (a / b) * b`. The sign of the non-zero remainder is the same as that of the left-hand operand, as the following example shows:

```
Console.WriteLine(5 % 4);    // output: 1
Console.WriteLine(5 % -4);   // output: 1
Console.WriteLine(-5 % 4);   // output: -1
Console.WriteLine(-5 % -4);  // output: -1
```

Use the [Math.DivRem](#) method to compute both integer division and remainder results.

Floating-point remainder

For the `float` and `double` operands, the result of `x % y` for the finite `x` and `y` is the value `z` such that

- The sign of `z`, if non-zero, is the same as the sign of `x`.
- The absolute value of `z` is the value produced by `|x| - n * |y|` where `n` is the largest possible integer that is less than or equal to `|x| / |y|` and `|x|` and `|y|` are the absolute values of `x` and `y`, respectively.

NOTE

This method of computing the remainder is analogous to that used for integer operands, but different from the IEEE 754 specification. If you need the remainder operation that complies with the IEEE 754 specification, use the [Math.IEEERemainder](#) method.

For information about the behavior of the `%` operator with non-finite operands, see the [Remainder operator](#) section of the [C# language specification](#).

For the `decimal` operands, the remainder operator `%` is equivalent to the [remainder operator](#) of the [System.Decimal](#) type.

The following example demonstrates the behavior of the remainder operator with floating-point operands:

```
Console.WriteLine(-5.2f % 2.0f); // output: -1.2
Console.WriteLine(5.9 % 3.1);    // output: 2.8
Console.WriteLine(5.9m % 3.1m); // output: 2.8
```

Addition operator +

The addition operator `+` computes the sum of its operands:

```
Console.WriteLine(5 + 4);          // output: 9
Console.WriteLine(5 + 4.3);        // output: 9.3
Console.WriteLine(5.1m + 4.2m);    // output: 9.3
```

You can also use the `+` operator for string concatenation and delegate combination. For more information, see the [+ and += operators](#) article.

Subtraction operator -

The subtraction operator `-` subtracts its right-hand operand from its left-hand operand:

```
Console.WriteLine(47 - 3);          // output: 44
Console.WriteLine(5 - 4.3);         // output: 0.7
Console.WriteLine(7.5m - 2.3m);     // output: 5.2
```

You can also use the `-` operator for delegate removal. For more information, see the [- and -= operators](#) article.

Compound assignment

For a binary operator `op`, a compound assignment expression of the form

```
x op= y
```

is equivalent to

```
x = x op y
```

except that `x` is only evaluated once.

The following example demonstrates the usage of compound assignment with arithmetic operators:

```
int a = 5;
a += 9;
Console.WriteLine(a); // output: 14

a -= 4;
Console.WriteLine(a); // output: 10

a *= 2;
Console.WriteLine(a); // output: 20

a /= 4;
Console.WriteLine(a); // output: 5

a %= 3;
Console.WriteLine(a); // output: 2
```

Because of [numeric promotions](#), the result of the `op` operation might be not implicitly convertible to the type `T` of `x`. In such a case, if `op` is a predefined operator and the result of the operation is explicitly convertible to the type `T` of `x`, a compound assignment expression of the form `x op= y` is equivalent to `x = (T)(x op y)`, except that `x` is only evaluated once. The following example demonstrates that behavior:

```
byte a = 200;
byte b = 100;

var c = a + b;
Console.WriteLine(c.GetType()); // output: System.Int32
Console.WriteLine(c); // output: 300

a += b;
Console.WriteLine(a); // output: 44
```

You also use the `+=` and `-=` operators to subscribe to and unsubscribe from an [event](#), respectively. For more information, see [How to subscribe to and unsubscribe from events](#).

Operator precedence and associativity

The following list orders arithmetic operators starting from the highest precedence to the lowest:

- Postfix increment `x++` and decrement `x--` operators
- Prefix increment `++x` and decrement `--x` and unary `+` and `-` operators
- Multiplicative `*`, `/`, and `%` operators
- Additive `+` and `-` operators

Binary arithmetic operators are left-associative. That is, operators with the same precedence level are evaluated from left to right.

Use parentheses, `()`, to change the order of evaluation imposed by operator precedence and associativity.

```
Console.WriteLine(2 + 2 * 2); // output: 6
Console.WriteLine((2 + 2) * 2); // output: 8

Console.WriteLine(9 / 5 / 2); // output: 0
Console.WriteLine(9 / (5 / 2)); // output: 4
```

For the complete list of C# operators ordered by precedence level, see the [Operator precedence](#) section of the [C# operators](#) article.

Arithmetic overflow and division by zero

When the result of an arithmetic operation is outside the range of possible finite values of the involved numeric type, the behavior of an arithmetic operator depends on the type of its operands.

Integer arithmetic overflow

Integer division by zero always throws a [DivideByZeroException](#).

In case of integer arithmetic overflow, an overflow checking context, which can be [checked](#) or [unchecked](#), controls the resulting behavior:

- In a checked context, if overflow happens in a constant expression, a compile-time error occurs. Otherwise, when the operation is performed at run time, an [OverflowException](#) is thrown.
- In an unchecked context, the result is truncated by discarding any high-order bits that don't fit in the destination type.

Along with the [checked](#) and [unchecked](#) statements, you can use the `checked` and `unchecked` operators to control the overflow checking context, in which an expression is evaluated:

```
int a = int.MaxValue;
int b = 3;

Console.WriteLine(unchecked(a + b)); // output: -2147483646
try
{
    int d = checked(a + b);
}
catch(OverflowException)
{
    Console.WriteLine($"Overflow occurred when adding {a} to {b}.");
}
```

By default, arithmetic operations occur in an *unchecked* context.

Floating-point arithmetic overflow

Arithmetic operations with the `float` and `double` types never throw an exception. The result of arithmetic operations with those types can be one of special values that represent infinity and not-a-number:

```
double a = 1.0 / 0.0;
Console.WriteLine(a); // output: Infinity
Console.WriteLine(double.IsInfinity(a)); // output: True

Console.WriteLine(double.MaxValue + double.MaxValue); // output: Infinity

double b = 0.0 / 0.0;
Console.WriteLine(b); // output: NaN
Console.WriteLine(double.IsNaN(b)); // output: True
```

For the operands of the `decimal` type, arithmetic overflow always throws an [OverflowException](#) and division by zero always throws a [DivideByZeroException](#).

Round-off errors

Because of general limitations of the floating-point representation of real numbers and floating-point arithmetic, round-off errors might occur in calculations with floating-point types. That is, the produced result of an expression might differ from the expected mathematical result. The following example demonstrates several such cases:

```
Console.WriteLine(.41f % .2f); // output: 0.00999999
```

```
double a = 0.1;  
double b = 3 * a;  
Console.WriteLine(b == 0.3);    // output: False  
Console.WriteLine(b - 0.3);     // output: 5.55111512312578E-17
```

```
decimal c = 1 / 3.0m;  
decimal d = 3 * c;  
Console.WriteLine(d == 1.0m);   // output: False  
Console.WriteLine(d);           // output: 0.999999999999999999999999999999
```

For more information, see remarks at the [System.Double](#), [System.Single](#), or [System.Decimal](#) reference pages.

Operator overloadability

A user-defined type can [overload](#) the unary (`++`, `--`, `+`, and `-`) and binary (`*`, `/`, `%`, `+`, and `-`) arithmetic operators. When a binary operator is overloaded, the corresponding compound assignment operator is also implicitly overloaded. A user-defined type cannot explicitly overload a compound assignment operator.

C# language specification

For more information, see the following sections of the [C# language specification](#):

- Postfix increment and decrement operators
- Prefix increment and decrement operators
- Unary plus operator
- Unary minus operator
- Multiplication operator
- Division operator
- Remainder operator
- Addition operator
- Subtraction operator
- Compound assignment
- The checked and unchecked operators

Boolean logical operators (C# reference)

12/28/2021 • 7 minutes to read • [Edit Online](#)

The following operators perform logical operations with `bool` operands:

- Unary `!` (logical negation) operator.
- Binary `&` (logical AND), `|` (logical OR), and `^` (logical exclusive OR) operators. Those operators always evaluate both operands.
- Binary `&&` (conditional logical AND) and `||` (conditional logical OR) operators. Those operators evaluate the right-hand operand only if it's necessary.

For operands of the [integral numeric types](#), the `&`, `|`, and `^` operators perform bitwise logical operations. For more information, see [Bitwise and shift operators](#).

Logical negation operator !

The unary prefix `!` operator computes logical negation of its operand. That is, it produces `true`, if the operand evaluates to `false`, and `false`, if the operand evaluates to `true`:

```
bool passed = false;
Console.WriteLine(!passed); // output: True
Console.WriteLine(!true);   // output: False
```

Beginning with C# 8.0, the unary postfix `!` operator is the [null-forgiving operator](#).

Logical AND operator &

The `&` operator computes the logical AND of its operands. The result of `x & y` is `true` if both `x` and `y` evaluate to `true`. Otherwise, the result is `false`.

The `&` operator evaluates both operands even if the left-hand operand evaluates to `false`, so that the operation result is `false` regardless of the value of the right-hand operand.

In the following example, the right-hand operand of the `&` operator is a method call, which is performed regardless of the value of the left-hand operand:

```
bool SecondOperand()
{
    Console.WriteLine("Second operand is evaluated.");
    return true;
}

bool a = false & SecondOperand();
Console.WriteLine(a);
// Output:
// Second operand is evaluated.
// False

bool b = true & SecondOperand();
Console.WriteLine(b);
// Output:
// Second operand is evaluated.
// True
```

The [conditional logical AND operator](#) `&&` also computes the logical AND of its operands, but doesn't evaluate the right-hand operand if the left-hand operand evaluates to `false`.

For operands of the [integral numeric types](#), the `&` operator computes the [bitwise logical AND](#) of its operands. The unary `&` operator is the [address-of operator](#).

Logical exclusive OR operator `^`

The `^` operator computes the logical exclusive OR, also known as the logical XOR, of its operands. The result of `x ^ y` is `true` if `x` evaluates to `true` and `y` evaluates to `false`, or `x` evaluates to `false` and `y` evaluates to `true`. Otherwise, the result is `false`. That is, for the `bool` operands, the `^` operator computes the same result as the [inequality operator](#) `!=`.

```
Console.WriteLine(true ^ true);    // output: False
Console.WriteLine(true ^ false);   // output: True
Console.WriteLine(false ^ true);   // output: True
Console.WriteLine(false ^ false);  // output: False
```

For operands of the [integral numeric types](#), the `^` operator computes the [bitwise logical exclusive OR](#) of its operands.

Logical OR operator `|`

The `|` operator computes the logical OR of its operands. The result of `x | y` is `true` if either `x` or `y` evaluates to `true`. Otherwise, the result is `false`.

The `|` operator evaluates both operands even if the left-hand operand evaluates to `true`, so that the operation result is `true` regardless of the value of the right-hand operand.

In the following example, the right-hand operand of the `|` operator is a method call, which is performed regardless of the value of the left-hand operand:

```
bool SecondOperand()
{
    Console.WriteLine("Second operand is evaluated.");
    return true;
}

bool a = true | SecondOperand();
Console.WriteLine(a);
// Output:
// Second operand is evaluated.
// True

bool b = false | SecondOperand();
Console.WriteLine(b);
// Output:
// Second operand is evaluated.
// True
```

The [conditional logical OR operator](#) `||` also computes the logical OR of its operands, but doesn't evaluate the right-hand operand if the left-hand operand evaluates to `true`.

For operands of the [integral numeric types](#), the `|` operator computes the [bitwise logical OR](#) of its operands.

Conditional logical AND operator `&&`

The conditional logical AND operator `&&`, also known as the "short-circuiting" logical AND operator, computes the logical AND of its operands. The result of `x && y` is `true` if both `x` and `y` evaluate to `true`. Otherwise, the result is `false`. If `x` evaluates to `false`, `y` is not evaluated.

In the following example, the right-hand operand of the `&&` operator is a method call, which isn't performed if the left-hand operand evaluates to `false`:

```
bool SecondOperand()
{
    Console.WriteLine("Second operand is evaluated.");
    return true;
}

bool a = false && SecondOperand();
Console.WriteLine(a);
// Output:
// False

bool b = true && SecondOperand();
Console.WriteLine(b);
// Output:
// Second operand is evaluated.
// True
```

The [logical AND operator](#) `&` also computes the logical AND of its operands, but always evaluates both operands.

Conditional logical OR operator `||`

The conditional logical OR operator `||`, also known as the "short-circuiting" logical OR operator, computes the logical OR of its operands. The result of `x || y` is `true` if either `x` or `y` evaluates to `true`. Otherwise, the result is `false`. If `x` evaluates to `true`, `y` is not evaluated.

In the following example, the right-hand operand of the `||` operator is a method call, which isn't performed if the left-hand operand evaluates to `true`:

```
bool SecondOperand()
{
    Console.WriteLine("Second operand is evaluated.");
    return true;
}

bool a = true || SecondOperand();
Console.WriteLine(a);
// Output:
// True

bool b = false || SecondOperand();
Console.WriteLine(b);
// Output:
// Second operand is evaluated.
// True
```

The [logical OR operator](#) `|` also computes the logical OR of its operands, but always evaluates both operands.

Nullable Boolean logical operators

For `bool?` operands, the `&` ([logical AND](#)) and `|` ([logical OR](#)) operators support the three-valued logic as follows:

- The `&` operator produces `true` only if both its operands evaluate to `true`. If either `x` or `y` evaluates to `false`, `x & y` produces `false` (even if another operand evaluates to `null`). Otherwise, the result of `x & y` is `null`.
- The `|` operator produces `false` only if both its operands evaluate to `false`. If either `x` or `y` evaluates to `true`, `x | y` produces `true` (even if another operand evaluates to `null`). Otherwise, the result of `x | y` is `null`.

The following table presents that semantics:

x	y	x&y	x y
true	true	true	true
true	false	false	true
true	null	null	true
false	true	false	true
false	false	false	false
false	null	false	null
null	true	null	true
null	false	false	null
null	null	null	null

The behavior of those operators differs from the typical operator behavior with nullable value types. Typically, an operator which is defined for operands of a value type can be also used with operands of the corresponding nullable value type. Such an operator produces `null` if any of its operands evaluates to `null`. However, the `&` and `|` operators can produce non-null even if one of the operands evaluates to `null`. For more information about the operator behavior with nullable value types, see the [Lifted operators](#) section of the [Nullable value types](#) article.

You can also use the `!` and `^` operators with `bool?` operands, as the following example shows:

```
bool? test = null;
Display(!test);           // output: null
Display(test ^ false);    // output: null
Display(test ^ null);     // output: null
Display(true ^ null);     // output: null

void Display(bool? b) => Console.WriteLine(b is null ? "null" : b.Value.ToString());
```

The conditional logical operators `&&` and `||` don't support `bool?` operands.

Compound assignment

For a binary operator `op`, a compound assignment expression of the form

```
x op= y
```

is equivalent to

```
x = x op y
```

except that `x` is only evaluated once.

The `&`, `|`, and `^` operators support compound assignment, as the following example shows:

```
bool test = true;
test &= false;
Console.WriteLine(test); // output: False

test |= true;
Console.WriteLine(test); // output: True

test ^= false;
Console.WriteLine(test); // output: True
```

NOTE

The conditional logical operators `&&` and `||` don't support compound assignment.

Operator precedence

The following list orders logical operators starting from the highest precedence to the lowest:

- Logical negation operator `!`
- Logical AND operator `&`
- Logical exclusive OR operator `^`
- Logical OR operator `|`
- Conditional logical AND operator `&&`
- Conditional logical OR operator `||`

Use parentheses, `()`, to change the order of evaluation imposed by operator precedence:

```
Console.WriteLine(true | true & false); // output: True
Console.WriteLine((true | true) & false); // output: False

bool Operand(string name, bool value)
{
    Console.WriteLine($"Operand {name} is evaluated.");
    return value;
}

var byDefaultPrecedence = Operand("A", true) || Operand("B", true) && Operand("C", false);
Console.WriteLine(byDefaultPrecedence);
// Output:
// Operand A is evaluated.
// True

var changedOrder = (Operand("A", true) || Operand("B", true)) && Operand("C", false);
Console.WriteLine(changedOrder);
// Output:
// Operand A is evaluated.
// Operand C is evaluated.
// False
```

For the complete list of C# operators ordered by precedence level, see the [Operator precedence](#) section of the [C# operators](#) article.

Operator overloadability

A user-defined type can [overload](#) the `!`, `&`, `|`, and `^` operators. When a binary operator is overloaded, the corresponding compound assignment operator is also implicitly overloaded. A user-defined type cannot explicitly overload a compound assignment operator.

A user-defined type cannot overload the conditional logical operators `&&` and `||`. However, if a user-defined type overloads the [true and false operators](#) and the `&` or `|` operator in a certain way, the `&&` or `||` operation, respectively, can be evaluated for the operands of that type. For more information, see the [User-defined conditional logical operators](#) section of the [C# language specification](#).

C# language specification

For more information, see the following sections of the [C# language specification](#):

- [Logical negation operator](#)
- [Logical operators](#)
- [Conditional logical operators](#)
- [Compound assignment](#)

See also

- [C# reference](#)
- [C# operators and expressions](#)
- [Bitwise and shift operators](#)

Bitwise and shift operators (C# reference)

12/28/2021 • 7 minutes to read • [Edit Online](#)

The following operators perform bitwise or shift operations with operands of the [integral numeric types](#) or the [char](#) type:

- Unary `~` ([bitwise complement](#)) operator
- Binary `<<` ([left shift](#)) and `>>` ([right shift](#)) shift operators
- Binary `&` ([logical AND](#)), `|` ([logical OR](#)), and `^` ([logical exclusive OR](#)) operators

Those operators are defined for the `int`, `uint`, `long`, and `ulong` types. When both operands are of other integral types (`sbyte`, `byte`, `short`, `ushort`, or `char`), their values are converted to the `int` type, which is also the result type of an operation. When operands are of different integral types, their values are converted to the closest containing integral type. For more information, see the [Numeric promotions](#) section of the [C# language specification](#).

The `&`, `|`, and `^` operators are also defined for operands of the `bool` type. For more information, see [Boolean logical operators](#).

Bitwise and shift operations never cause overflow and produce the same results in [checked and unchecked](#) contexts.

Bitwise complement operator `~`

The `~` operator produces a bitwise complement of its operand by reversing each bit:

```
uint a = 0b_0000_1111_0000_1111_0000_1111_0000_1100;
uint b = ~a;
Console.WriteLine(Convert.ToString(b, toBase: 2));
// Output:
// 11110000111100001111000011110011
```

You can also use the `~` symbol to declare finalizers. For more information, see [Finalizers](#).

Left-shift operator `<<`

The `<<` operator shifts its left-hand operand left by the number of bits defined by its right-hand operand. For information about how the right-hand operand defines the shift count, see the [Shift count of the shift operators](#) section.

The left-shift operation discards the high-order bits that are outside the range of the result type and sets the low-order empty bit positions to zero, as the following example shows:

```
uint x = 0b_1100_1001_0000_0000_0000_0000_0001_0001;
Console.WriteLine($"Before: {Convert.ToString(x, toBase: 2)}");

uint y = x << 4;
Console.WriteLine($"After: {Convert.ToString(y, toBase: 2)}");
// Output:
// Before: 110010010000000000000000000010001
// After:  100100000000000000000000100010000
```

Because the shift operators are defined only for the `int`, `uint`, `long`, and `ulong` types, the result of an operation always contains at least 32 bits. If the left-hand operand is of another integral type (`sbyte`, `byte`, `short`, `ushort`, or `char`), its value is converted to the `int` type, as the following example shows:

```
byte a = 0b_1111_0001;

var b = a << 8;
Console.WriteLine(b.GetType());
Console.WriteLine($"Shifted byte: {Convert.ToString(b, toBase: 2)}");
// Output:
// System.Int32
// Shifted byte: 1111000100000000
```

Right-shift operator >>

The `>>` operator shifts its left-hand operand right by the number of bits defined by its right-hand operand. For information about how the right-hand operand defines the shift count, see the [Shift count of the shift operators](#) section.

The right-shift operation discards the low-order bits, as the following example shows:

```
uint x = 0b_1001;
Console.WriteLine($"Before: {Convert.ToString(x, toBase: 2), 4}");

uint y = x >> 2;
Console.WriteLine($"After: {Convert.ToString(y, toBase: 2), 4}");
// Output:
// Before: 1001
// After:  10
```

The high-order empty bit positions are set based on the type of the left-hand operand as follows:

- If the left-hand operand is of type `int` or `long`, the right-shift operator performs an *arithmetic* shift: the value of the most significant bit (the sign bit) of the left-hand operand is propagated to the high-order empty bit positions. That is, the high-order empty bit positions are set to zero if the left-hand operand is non-negative and set to one if it's negative.

```
int a = int.MinValue;
Console.WriteLine($"Before: {Convert.ToString(a, toBase: 2)}");

int b = a >> 3;
Console.WriteLine($"After: {Convert.ToString(b, toBase: 2)}");
// Output:
// Before: 10000000000000000000000000000000
// After:  11110000000000000000000000000000
```

- If the left-hand operand is of type `uint` or `ulong`, the right-shift operator performs a *logical* shift: the high-order empty bit positions are always set to zero.

```
uint c = 0b_1000_0000_0000_0000_0000_0000_0000_0000;
Console.WriteLine($"Before: {Convert.ToString(c, toBase: 2), 32}");

uint d = c >> 3;
Console.WriteLine($"After: {Convert.ToString(d, toBase: 2), 32}");
// Output:
// Before: 10000000000000000000000000000000
// After:  10000000000000000000000000000000
```

Logical AND operator &

The `&` operator computes the bitwise logical AND of its integral operands:

```
uint a = 0b_1111_1000;
uint b = 0b_1001_1101;
uint c = a & b;
Console.WriteLine(Convert.ToString(c, toBase: 2));
// Output:
// 10011000
```

For `bool` operands, the `&` operator computes the [logical AND](#) of its operands. The unary `&` operator is the [address-of operator](#).

Logical exclusive OR operator ^

The `^` operator computes the bitwise logical exclusive OR, also known as the bitwise logical XOR, of its integral operands:

```
uint a = 0b_1111_1000;
uint b = 0b_0001_1100;
uint c = a ^ b;
Console.WriteLine(Convert.ToString(c, toBase: 2));
// Output:
// 11100100
```

For `bool` operands, the `^` operator computes the [logical exclusive OR](#) of its operands.

Logical OR operator |

The `|` operator computes the bitwise logical OR of its integral operands:

```
uint a = 0b_1010_0000;
uint b = 0b_1001_0001;
uint c = a | b;
Console.WriteLine(Convert.ToString(c, toBase: 2));
// Output:
// 10110001
```

For `bool` operands, the `|` operator computes the [logical OR](#) of its operands.

Compound assignment

For a binary operator `op`, a compound assignment expression of the form

```
x op= y
```

is equivalent to

```
x = x op y
```

except that `x` is only evaluated once.

The following example demonstrates the usage of compound assignment with bitwise and shift operators:

```

uint INITIAL_VALUE = 0b_1111_1000;

uint a = INITIAL_VALUE;
a &= 0b_1001_1101;
Display(a); // output: 10011000

a = INITIAL_VALUE;
a |= 0b_0011_0001;
Display(a); // output: 11111001

a = INITIAL_VALUE;
a ^= 0b_1000_0000;
Display(a); // output: 1111000

a = INITIAL_VALUE;
a <<= 2;
Display(a); // output: 1111100000

a = INITIAL_VALUE;
a >>= 4;
Display(a); // output: 1111

void Display(uint x) => Console.WriteLine($"{Convert.ToString(x, toBase: 2), 8}");

```

Because of [numeric promotions](#), the result of the `op` operation might be not implicitly convertible to the type `T` of `x`. In such a case, if `op` is a predefined operator and the result of the operation is explicitly convertible to the type `T` of `x`, a compound assignment expression of the form `x op= y` is equivalent to `x = (T)(x op y)`, except that `x` is only evaluated once. The following example demonstrates that behavior:

```

byte x = 0b_1111_0001;

int b = x << 8;
Console.WriteLine($"{Convert.ToString(b, toBase: 2)}"); // output: 1111000100000000

x <<= 8;
Console.WriteLine(x); // output: 0

```

Operator precedence

The following list orders bitwise and shift operators starting from the highest precedence to the lowest:

- Bitwise complement operator `~`
- Shift operators `<<` and `>>`
- Logical AND operator `&`
- Logical exclusive OR operator `^`
- Logical OR operator `|`

Use parentheses, `()`, to change the order of evaluation imposed by operator precedence:

```

uint a = 0b_1101;
uint b = 0b_1001;
uint c = 0b_1010;

uint d1 = a | b & c;
Display(d1); // output: 1101

uint d2 = (a | b) & c;
Display(d2); // output: 1000

void Display(uint x) => Console.WriteLine($"{Convert.ToString(x, toBase: 2), 4}");

```

For the complete list of C# operators ordered by precedence level, see the [Operator precedence](#) section of the [C# operators](#) article.

Shift count of the shift operators

For the shift operators `<<` and `>>`, the type of the right-hand operand must be `int` or a type that has a [predefined implicit numeric conversion](#) to `int`.

For the `x << count` and `x >> count` expressions, the actual shift count depends on the type of `x` as follows:

- If the type of `x` is `int` or `uint`, the shift count is defined by the low-order *five* bits of the right-hand operand. That is, the shift count is computed from `count & 0x1F` (or `count & 0b_1_1111`).
- If the type of `x` is `long` or `ulong`, the shift count is defined by the low-order *six* bits of the right-hand operand. That is, the shift count is computed from `count & 0x3F` (or `count & 0b_11_1111`).

The following example demonstrates that behavior:

```

int count1 = 0b_0000_0001;
int count2 = 0b_1110_0001;

int a = 0b_0001;
Console.WriteLine($"{a} << {count1} is {a << count1}; {a} << {count2} is {a << count2}");
// Output:
// 1 << 1 is 2; 1 << 225 is 2

int b = 0b_0100;
Console.WriteLine($"{b} >> {count1} is {b >> count1}; {b} >> {count2} is {b >> count2}");
// Output:
// 4 >> 1 is 2; 4 >> 225 is 2

```

NOTE

As the preceding example shows, the result of a shift operation can be non-zero even if the value of the right-hand operand is greater than the number of bits in the left-hand operand.

Enumeration logical operators

The `~`, `&`, `|`, and `^` operators are also supported by any [enumeration](#) type. For operands of the same enumeration type, a logical operation is performed on the corresponding values of the underlying integral type. For example, for any `x` and `y` of an enumeration type `T` with an underlying type `U`, the `x & y` expression produces the same result as the `(T)((U)x & (U)y)` expression.

You typically use bitwise logical operators with an enumeration type that is defined with the [Flags](#) attribute. For more information, see the [Enumeration types as bit flags](#) section of the [Enumeration types](#) article.

Operator overloadability

A user-defined type can [overload](#) the `~`, `<<`, `>>`, `&`, `|`, and `^` operators. When a binary operator is overloaded, the corresponding compound assignment operator is also implicitly overloaded. A user-defined type cannot explicitly overload a compound assignment operator.

If a user-defined type `T` overloads the `<<` or `>>` operator, the type of the left-hand operand must be `T` and the type of the right-hand operand must be `int`.

C# language specification

For more information, see the following sections of the [C# language specification](#):

- [Bitwise complement operator](#)
- [Shift operators](#)
- [Logical operators](#)
- [Compound assignment](#)
- [Numeric promotions](#)

Equality operators (C# reference)

12/28/2021 • 4 minutes to read • [Edit Online](#)

The `==` (equality) and `!=` (inequality) operators check if their operands are equal or not.

Equality operator `==`

The equality operator `==` returns `true` if its operands are equal, `false` otherwise.

Value types equality

Operands of the [built-in value types](#) are equal if their values are equal:

```
int a = 1 + 2 + 3;
int b = 6;
Console.WriteLine(a == b); // output: True

char c1 = 'a';
char c2 = 'A';
Console.WriteLine(c1 == c2); // output: False
Console.WriteLine(c1 == char.ToLower(c2)); // output: True
```

NOTE

For the `==`, `<`, `>`, `<=`, and `>=` operators, if any of the operands is not a number ([Double.NaN](#) or [Single.NaN](#)), the result of operation is `false`. That means that the `NaN` value is neither greater than, less than, nor equal to any other `double` (or `float`) value, including `NaN`. For more information and examples, see the [Double.NaN](#) or [Single.NaN](#) reference article.

Two operands of the same [enum](#) type are equal if the corresponding values of the underlying integral type are equal.

User-defined [struct](#) types don't support the `==` operator by default. To support the `==` operator, a user-defined struct must [overload](#) it.

Beginning with C# 7.3, the `==` and `!=` operators are supported by C# [tuples](#). For more information, see the [Tuple equality](#) section of the [Tuple types](#) article.

Reference types equality

By default, two non-record reference-type operands are equal if they refer to the same object:

```

public class ReferenceTypesEquality
{
    public class MyClass
    {
        private int id;

        public MyClass(int id) => this.id = id;
    }

    public static void Main()
    {
        var a = new MyClass(1);
        var b = new MyClass(1);
        var c = a;
        Console.WriteLine(a == b); // output: False
        Console.WriteLine(a == c); // output: True
    }
}

```

As the example shows, user-defined reference types support the `==` operator by default. However, a reference type can overload the `==` operator. If a reference type overloads the `==` operator, use the [Object.ReferenceEquals](#) method to check if two references of that type refer to the same object.

Record types equality

Available in C# 9.0 and later, [record types](#) support the `==` and `!=` operators that by default provide value equality semantics. That is, two record operands are equal when both of them are `null` or corresponding values of all fields and auto-implemented properties are equal.

```

public class RecordTypesEquality
{
    public record Point(int X, int Y, string Name);
    public record TaggedNumber(int Number, List<string> Tags);

    public static void Main()
    {
        var p1 = new Point(2, 3, "A");
        var p2 = new Point(1, 3, "B");
        var p3 = new Point(2, 3, "A");

        Console.WriteLine(p1 == p2); // output: False
        Console.WriteLine(p1 == p3); // output: True

        var n1 = new TaggedNumber(2, new List<string>() { "A" });
        var n2 = new TaggedNumber(2, new List<string>() { "A" });
        Console.WriteLine(n1 == n2); // output: False
    }
}

```

As the preceding example shows, in case of non-record reference-type members their reference values are compared, not the referenced instances.

String equality

Two [string](#) operands are equal when both of them are `null` or both string instances are of the same length and have identical characters in each character position:

```
string s1 = "hello!";
string s2 = "HeLLo!";
Console.WriteLine(s1 == s2.ToLower()); // output: True

string s3 = "Hello!";
Console.WriteLine(s1 == s3); // output: False
```

That is a case-sensitive ordinal comparison. For more information about string comparison, see [How to compare strings in C#](#).

Delegate equality

Two [delegate](#) operands of the same run-time type are equal when both of them are `null` or their invocation lists are of the same length and have equal entries in each position:

```
Action a = () => Console.WriteLine("a");

Action b = a + a;
Action c = a + a;
Console.WriteLine(object.ReferenceEquals(b, c)); // output: False
Console.WriteLine(b == c); // output: True
```

For more information, see the [Delegate equality operators](#) section of the [C# language specification](#).

Delegates that are produced from evaluation of semantically identical [lambda expressions](#) are not equal, as the following example shows:

```
Action a = () => Console.WriteLine("a");
Action b = () => Console.WriteLine("a");

Console.WriteLine(a == b); // output: False
Console.WriteLine(a + b == a + b); // output: True
Console.WriteLine(b + a == a + b); // output: False
```

Inequality operator !=

The inequality operator `!=` returns `true` if its operands are not equal, `false` otherwise. For the operands of the [built-in types](#), the expression `x != y` produces the same result as the expression `!(x == y)`. For more information about type equality, see the [Equality operator](#) section.

The following example demonstrates the usage of the `!=` operator:

```
int a = 1 + 1 + 2 + 3;
int b = 6;
Console.WriteLine(a != b); // output: True

string s1 = "Hello";
string s2 = "Hello";
Console.WriteLine(s1 != s2); // output: False

object o1 = 1;
object o2 = 1;
Console.WriteLine(o1 != o2); // output: True
```

Operator overloadability

A user-defined type can [overload](#) the `==` and `!=` operators. If a type overloads one of the two operators, it

must also overload the other one.

A record type cannot explicitly overload the `==` and `!=` operators. If you need to change the behavior of the `==` and `!=` operators for record type `T`, implement the [IEquatable<T>.Equals](#) method with the following signature:

```
public virtual bool Equals(T? other);
```

C# language specification

For more information, see the [Relational and type-testing operators](#) section of the [C# language specification](#).

For more information about equality of record types, see the [Equality members](#) section of the [records feature proposal note](#).

See also

- [C# reference](#)
- [C# operators and expressions](#)
- [System.IEquatable<T>](#)
- [Object.Equals](#)
- [Object.ReferenceEquals](#)
- [Equality comparisons](#)
- [Comparison operators](#)

Comparison operators (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `<` (less than), `>` (greater than), `<=` (less than or equal), and `>=` (greater than or equal) comparison, also known as relational, operators compare their operands. Those operators are supported by all [integral](#) and [floating-point](#) numeric types.

NOTE

For the `==`, `<`, `>`, `<=`, and `>=` operators, if any of the operands is not a number ([Double.NaN](#) or [Single.NaN](#)), the result of operation is `false`. That means that the `NaN` value is neither greater than, less than, nor equal to any other `double` (or `float`) value, including `NaN`. For more information and examples, see the [Double.NaN](#) or [Single.NaN](#) reference article.

The [char](#) type also supports comparison operators. In the case of `char` operands, the corresponding character codes are compared.

Enumeration types also support comparison operators. For operands of the same [enum](#) type, the corresponding values of the underlying integral type are compared.

The `==` and `!=` operators check if their operands are equal or not.

Less than operator <

The `<` operator returns `true` if its left-hand operand is less than its right-hand operand, `false` otherwise:

```
Console.WriteLine(7.0 < 5.1); // output: False
Console.WriteLine(5.1 < 5.1); // output: False
Console.WriteLine(0.0 < 5.1); // output: True

Console.WriteLine(double.NaN < 5.1); // output: False
Console.WriteLine(double.NaN >= 5.1); // output: False
```

Greater than operator >

The `>` operator returns `true` if its left-hand operand is greater than its right-hand operand, `false` otherwise:

```
Console.WriteLine(7.0 > 5.1); // output: True
Console.WriteLine(5.1 > 5.1); // output: False
Console.WriteLine(0.0 > 5.1); // output: False

Console.WriteLine(double.NaN > 5.1); // output: False
Console.WriteLine(double.NaN <= 5.1); // output: False
```

Less than or equal operator <=

The `<=` operator returns `true` if its left-hand operand is less than or equal to its right-hand operand, `false` otherwise:

```
Console.WriteLine(7.0 <= 5.1);    // output: False
Console.WriteLine(5.1 <= 5.1);    // output: True
Console.WriteLine(0.0 <= 5.1);    // output: True

Console.WriteLine(double.NaN > 5.1);    // output: False
Console.WriteLine(double.NaN <= 5.1);    // output: False
```

Greater than or equal operator >=

The `>=` operator returns `true` if its left-hand operand is greater than or equal to its right-hand operand, `false` otherwise:

```
Console.WriteLine(7.0 >= 5.1);    // output: True
Console.WriteLine(5.1 >= 5.1);    // output: True
Console.WriteLine(0.0 >= 5.1);    // output: False

Console.WriteLine(double.NaN < 5.1);    // output: False
Console.WriteLine(double.NaN >= 5.1);    // output: False
```

Operator overloadability

A user-defined type can [overload](#) the `<`, `>`, `<=`, and `>=` operators.

If a type overloads one of the `<` or `>` operators, it must overload both `<` and `>`. If a type overloads one of the `<=` or `>=` operators, it must overload both `<=` and `>=`.

C# language specification

For more information, see the [Relational and type-testing operators](#) section of the [C# language specification](#).

Member access operators and expressions (C# reference)

12/28/2021 • 8 minutes to read • [Edit Online](#)

You can use the following operators and expressions when you access a type member:

- `.` ([member access](#)): to access a member of a namespace or a type
- `[]` ([array element or indexer access](#)): to access an array element or a type indexer
- `?.` and `?[]` ([null-conditional operators](#)): to perform a member or element access operation only if an operand is non-null
- `()` ([invocation](#)): to call an accessed method or invoke a delegate
- `^` ([index from end](#)): to indicate that the element position is from the end of a sequence
- `..` ([range](#)): to specify a range of indices that you can use to obtain a range of sequence elements

Member access expression `.`

You use the `.` token to access a member of a namespace or a type, as the following examples demonstrate:

- Use `.` to access a nested namespace within a namespace, as the following example of a `using` directive shows:

```
using System.Collections.Generic;
```

- Use `.` to form a *qualified name* to access a type within a namespace, as the following code shows:

```
System.Collections.Generic.IEnumerable<int> numbers = new int[] { 1, 2, 3 };
```

Use a `using` directive to make the use of qualified names optional.

- Use `.` to access [type members](#), static and non-static, as the following code shows:

```
var constants = new List<double>();
constants.Add(Math.PI);
constants.Add(Math.E);
Console.WriteLine($"{constants.Count} values to show:");
Console.WriteLine(string.Join(", ", constants));
// Output:
// 2 values to show:
// 3.14159265358979, 2.71828182845905
```

You can also use `.` to access an [extension method](#).

Indexer operator `[]`

Square brackets, `[]`, are typically used for array, indexer, or pointer element access.

Array access

The following example demonstrates how to access array elements:

```
int[] fib = new int[10];
fib[0] = fib[1] = 1;
for (int i = 2; i < fib.Length; i++)
{
    fib[i] = fib[i - 1] + fib[i - 2];
}
Console.WriteLine(fib[fib.Length - 1]); // output: 55

double[,] matrix = new double[2,2];
matrix[0,0] = 1.0;
matrix[0,1] = 2.0;
matrix[1,0] = matrix[1,1] = 3.0;
var determinant = matrix[0,0] * matrix[1,1] - matrix[1,0] * matrix[0,1];
Console.WriteLine(determinant); // output: -3
```

If an array index is outside the bounds of the corresponding dimension of an array, an [IndexOutOfRangeException](#) is thrown.

As the preceding example shows, you also use square brackets when you declare an array type or instantiate an array instance.

For more information about arrays, see [Arrays](#).

Indexer access

The following example uses the .NET [Dictionary<TKey,TValue>](#) type to demonstrate indexer access:

```
var dict = new Dictionary<string, double>();
dict["one"] = 1;
dict["pi"] = Math.PI;
Console.WriteLine(dict["one"] + dict["pi"]); // output: 4.14159265358979
```

Indexers allow you to index instances of a user-defined type in the similar way as array indexing. Unlike array indices, which must be integer, the indexer parameters can be declared to be of any type.

For more information about indexers, see [Indexers](#).

Other usages of []

For information about pointer element access, see the [Pointer element access operator \[\]](#) section of the [Pointer related operators](#) article.

You also use square brackets to specify [attributes](#):

```
[System.Diagnostics.Conditional("DEBUG")]
void TraceMethod() {}
```

Null-conditional operators ?. and ?[]

Available in C# 6 and later, a null-conditional operator applies a [member access](#), `?.`, or [element access](#), `?[]`, operation to its operand only if that operand evaluates to non-null; otherwise, it returns `null`. That is,

- If `a` evaluates to `null`, the result of `a?.x` or `a?[x]` is `null`.
- If `a` evaluates to non-null, the result of `a?.x` or `a?[x]` is the same as the result of `a.x` or `a[x]`, respectively.

NOTE

If `a.x` or `a[x]` throws an exception, `a?.x` or `a?[x]` would throw the same exception for non-null `a`. For example, if `a` is a non-null array instance and `x` is outside the bounds of `a`, `a?[x]` would throw an [IndexOutOfRangeException](#).

The null-conditional operators are short-circuiting. That is, if one operation in a chain of conditional member or element access operations returns `null`, the rest of the chain doesn't execute. In the following example, `B` is not evaluated if `A` evaluates to `null` and `C` is not evaluated if `A` or `B` evaluates to `null`:

```
A?.B?.Do(C);
A?.B?[C];
```

If `A` might be null but `B` and `C` would not be null if `A` is not null, you only need to apply the null-conditional operator to `A`:

```
A?.B.C();
```

In the preceding example, `B` is not evaluated and `C()` is not called if `A` is null. However, if the chained member access is interrupted, for example by parentheses as in `(A?.B).C()`, short-circuiting doesn't happen.

The following examples demonstrate the usage of the `?.` and `?[]` operators:

```
double SumNumbers(List<double[]> setsOfNumbers, int indexOfSetToSum)
{
    return setsOfNumbers?[indexOfSetToSum]?.Sum() ?? double.NaN;
}

var sum1 = SumNumbers(null, 0);
Console.WriteLine(sum1); // output: NaN

var numberSets = new List<double[]>
{
    new[] { 1.0, 2.0, 3.0 },
    null
};

var sum2 = SumNumbers(numberSets, 0);
Console.WriteLine(sum2); // output: 6

var sum3 = SumNumbers(numberSets, 1);
Console.WriteLine(sum3); // output: NaN
```

```

using System;
using System.Collections.Generic;
using System.Linq;

namespace MemberAccessOperators2
{
    public static class NullConditionalShortCircuiting
    {
        public static void Main()
        {
            Person person = null;
            person?.Name.Write(); // no output: Write() is not called due to short-circuit.
            try
            {
                (person?.Name).Write();
            }
            catch (NullReferenceException)
            {
                Console.WriteLine("NullReferenceException");
            }
            // output: NullReferenceException
        }
    }

    public class Person
    {
        public FullName Name { get; set; }
    }

    public class FullName
    {
        public string FirstName { get; set; }
        public string LastName { get; set; }
        public void Write()
        {
            Console.WriteLine($"{FirstName} {LastName}");
        }
    }
}

```

The first of the preceding two examples also uses the [null-coalescing operator](#) `??` to specify an alternative expression to evaluate in case the result of a null-conditional operation is `null`.

If `a.x` or `a[x]` is of a non-nullable value type `T`, `a?.x` or `a?[x]` is of the corresponding [nullable value type](#) `T?`. If you need an expression of type `T`, apply the null-coalescing operator `??` to a null-conditional expression, as the following example shows:

```

int GetSumOfFirstTwoOrDefault(int[] numbers)
{
    if ((numbers?.Length ?? 0) < 2)
    {
        return 0;
    }
    return numbers[0] + numbers[1];
}

Console.WriteLine(GetSumOfFirstTwoOrDefault(null)); // output: 0
Console.WriteLine(GetSumOfFirstTwoOrDefault(new int[0])); // output: 0
Console.WriteLine(GetSumOfFirstTwoOrDefault(new[] { 3, 4, 5 })); // output: 7

```

In the preceding example, if you don't use the `??` operator, `numbers?.Length < 2` evaluates to `false` when `numbers` is `null`.

The null-conditional member access operator `?.` is also known as the Elvis operator.

Thread-safe delegate invocation

Use the `?.` operator to check if a delegate is non-null and invoke it in a thread-safe way (for example, when you [raise an event](#)), as the following code shows:

```
PropertyChanged?.Invoke(...)
```

That code is equivalent to the following code that you would use in C# 5 or earlier:

```
var handler = this.PropertyChanged;  
if (handler != null)  
{  
    handler(...);  
}
```

That is a thread-safe way to ensure that only a non-null `handler` is invoked. Because delegate instances are immutable, no thread can change the object referenced by the `handler` local variable. In particular, if the code executed by another thread unsubscribes from the `PropertyChanged` event and `PropertyChanged` becomes `null` before `handler` is invoked, the object referenced by `handler` remains unaffected. The `?.` operator evaluates its left-hand operand no more than once, guaranteeing that it cannot be changed to `null` after being verified as non-null.

Invocation expression ()

Use parentheses, `()`, to call a [method](#) or invoke a [delegate](#).

The following example demonstrates how to call a method, with or without arguments, and invoke a delegate:

```
Action<int> display = s => Console.WriteLine(s);  
  
var numbers = new List<int>();  
numbers.Add(10);  
numbers.Add(17);  
display(numbers.Count); // output: 2  
  
numbers.Clear();  
display(numbers.Count); // output: 0
```

You also use parentheses when you invoke a [constructor](#) with the `new` operator.

Other usages of ()

You also use parentheses to adjust the order in which to evaluate operations in an expression. For more information, see [C# operators](#).

[Cast expressions](#), which perform explicit type conversions, also use parentheses.

Index from end operator ^

Available in C# 8.0 and later, the `^` operator indicates the element position from the end of a sequence. For a sequence of length `length`, `^n` points to the element with offset `length - n` from the start of a sequence. For example, `^1` points to the last element of a sequence and `^length` points to the first element of a sequence.

```
int[] xs = new[] { 0, 10, 20, 30, 40 };
int last = xs[^1];
Console.WriteLine(last); // output: 40

var lines = new List<string> { "one", "two", "three", "four" };
string prelast = lines[^2];
Console.WriteLine(prelast); // output: three

string word = "Twenty";
Index toFirst = ^word.Length;
char first = word[toFirst];
Console.WriteLine(first); // output: T
```

As the preceding example shows, expression `^e` is of the [System.Index](#) type. In expression `^e`, the result of `e` must be implicitly convertible to `int`.

You can also use the `^` operator with the [range operator](#) to create a range of indices. For more information, see [Indices and ranges](#).

Range operator ..

Available in C# 8.0 and later, the `..` operator specifies the start and end of a range of indices as its operands. The left-hand operand is an *inclusive* start of a range. The right-hand operand is an *exclusive* end of a range. Either of operands can be an index from the start or from the end of a sequence, as the following example shows:

```
int[] numbers = new[] { 0, 10, 20, 30, 40, 50 };
int start = 1;
int amountToTake = 3;
int[] subset = numbers[start..(start + amountToTake)];
Display(subset); // output: 10 20 30

int margin = 1;
int[] inner = numbers[margin..^margin];
Display(inner); // output: 10 20 30 40

string line = "one two three";
int amountToTakeFromEnd = 5;
Range endIndices = ^amountToTakeFromEnd..^0;
string end = line[endIndices];
Console.WriteLine(end); // output: three

void Display<T>(IEnumerable<T> xs) => Console.WriteLine(string.Join(" ", xs));
```

As the preceding example shows, expression `a..b` is of the [System.Range](#) type. In expression `a..b`, the results of `a` and `b` must be implicitly convertible to `int` or [Index](#).

You can omit any of the operands of the `..` operator to obtain an open-ended range:

- `a..` is equivalent to `a..^0`
- `..b` is equivalent to `0..b`
- `..` is equivalent to `0..^0`

```
int[] numbers = new[] { 0, 10, 20, 30, 40, 50 };
int amountToDrop = numbers.Length / 2;

int[] rightHalf = numbers[amountToDrop..];
Display(rightHalf); // output: 30 40 50

int[] leftHalf = numbers[..^amountToDrop];
Display(leftHalf); // output: 0 10 20

int[] all = numbers[..];
Display(all); // output: 0 10 20 30 40 50

void Display<T>(IEnumerable<T> xs) => Console.WriteLine(string.Join(" ", xs));
```

For more information, see [Indices and ranges](#).

Operator overloadability

The `.`, `()`, `^`, and `..` operators cannot be overloaded. The `[]` operator is also considered a non-overloadable operator. Use [indexers](#) to support indexing with user-defined types.

C# language specification

For more information, see the following sections of the [C# language specification](#):

- [Member access](#)
- [Element access](#)
- [Null-conditional operator](#)
- [Invocation expressions](#)

For more information about indices and ranges, see the [feature proposal note](#).

Type-testing operators and cast expression (C# reference)

12/28/2021 • 6 minutes to read • [Edit Online](#)

You can use the following operators and expressions to perform type checking or type conversion:

- **is operator**: Check if the run-time type of an expression is compatible with a given type
- **as operator**: Explicitly convert an expression to a given type if its run-time type is compatible with that type
- **cast expression**: Perform an explicit conversion
- **typeof operator**: Obtain the [System.Type](#) instance for a type

is operator

The `is` operator checks if the run-time type of an expression result is compatible with a given type. Beginning with C# 7.0, the `is` operator also tests an expression result against a pattern.

The expression with the type-testing `is` operator has the following form

```
E is T
```

where `E` is an expression that returns a value and `T` is the name of a type or a type parameter. `E` can't be an anonymous method or a lambda expression.

The `is` operator returns `true` when an expression result is non-null and any of the following conditions are true:

- The run-time type of an expression result is `T`.
- The run-time type of an expression result derives from type `T`, implements interface `T`, or another [implicit reference conversion](#) exists from it to `T`.
- The run-time type of an expression result is a [nullable value type](#) with the underlying type `T` and the `Nullable<T>.HasValue` is `true`.
- A [boxing](#) or [unboxing](#) conversion exists from the run-time type of an expression result to type `T`.

The `is` operator doesn't consider user-defined conversions.

The following example demonstrates that the `is` operator returns `true` if the run-time type of an expression result derives from a given type, that is, there exists a reference conversion between types:

```

public class Base { }

public class Derived : Base { }

public static class IsOperatorExample
{
    public static void Main()
    {
        object b = new Base();
        Console.WriteLine(b is Base); // output: True
        Console.WriteLine(b is Derived); // output: False

        object d = new Derived();
        Console.WriteLine(d is Base); // output: True
        Console.WriteLine(d is Derived); // output: True
    }
}

```

The next example shows that the `is` operator takes into account boxing and unboxing conversions but doesn't consider [numeric conversions](#):

```

int i = 27;
Console.WriteLine(i is System.IFormattable); // output: True

object iBoxed = i;
Console.WriteLine(iBoxed is int); // output: True
Console.WriteLine(iBoxed is long); // output: False

```

For information about C# conversions, see the [Conversions](#) chapter of the [C# language specification](#).

Type testing with pattern matching

Beginning with C# 7.0, the `is` operator also tests an expression result against a pattern. The following example shows how to use a [declaration pattern](#) to check the run-time type of an expression:

```

int i = 23;
object iBoxed = i;
int? jNullable = 7;
if (iBoxed is int a && jNullable is int b)
{
    Console.WriteLine(a + b); // output 30
}

```

For information about the supported patterns, see [Patterns](#).

as operator

The `as` operator explicitly converts the result of an expression to a given reference or nullable value type. If the conversion isn't possible, the `as` operator returns `null`. Unlike a [cast expression](#), the `as` operator never throws an exception.

The expression of the form

```
E as T
```

where `E` is an expression that returns a value and `T` is the name of a type or a type parameter, produces the same result as

```
E is T ? (T)(E) : (T)null
```

except that `E` is only evaluated once.

The `as` operator considers only reference, nullable, boxing, and unboxing conversions. You can't use the `as` operator to perform a user-defined conversion. To do that, use a [cast expression](#).

The following example demonstrates the usage of the `as` operator:

```
IEnumerable<int> numbers = new[] { 10, 20, 30 };
IList<int> indexable = numbers as IList<int>;
if (indexable != null)
{
    Console.WriteLine(indexable[0] + indexable[indexable.Count - 1]); // output: 40
}
```

NOTE

As the preceding example shows, you need to compare the result of the `as` expression with `null` to check if the conversion is successful. Beginning with C# 7.0, you can use the [is operator](#) both to test if the conversion succeeds and, if it succeeds, assign its result to a new variable.

Cast expression

A cast expression of the form `(T)E` performs an explicit conversion of the result of expression `E` to type `T`. If no explicit conversion exists from the type of `E` to type `T`, a compile-time error occurs. At run time, an explicit conversion might not succeed and a cast expression might throw an exception.

The following example demonstrates explicit numeric and reference conversions:

```
double x = 1234.7;
int a = (int)x;
Console.WriteLine(a); // output: 1234

IEnumerable<int> numbers = new int[] { 10, 20, 30 };
IList<int> list = (IList<int>)numbers;
Console.WriteLine(list.Count); // output: 3
Console.WriteLine(list[1]); // output: 20
```

For information about supported explicit conversions, see the [Explicit conversions](#) section of the [C# language specification](#). For information about how to define a custom explicit or implicit type conversion, see [User-defined conversion operators](#).

Other usages of ()

You also use parentheses to [call a method or invoke a delegate](#).

Other use of parentheses is to adjust the order in which to evaluate operations in an expression. For more information, see [C# operators](#).

typeof operator

The `typeof` operator obtains the [System.Type](#) instance for a type. The argument to the `typeof` operator must be the name of a type or a type parameter, as the following example shows:

```

void PrintType<T>() => Console.WriteLine(typeof(T));

Console.WriteLine(typeof(List<string>));
PrintType<int>();
PrintType<System.Int32>();
PrintType<Dictionary<int, char>>();
// Output:
// System.Collections.Generic.List`1[System.String]
// System.Int32
// System.Int32
// System.Collections.Generic.Dictionary`2[System.Int32,System.Char]

```

The argument mustn't be a type that requires metadata annotations. Examples include the following types:

- `dynamic`
- `string?` (or any nullable reference type)

These types aren't directly represented in metadata. The types include attributes that describe the underlying type. In both cases, you can use the underlying type. Instead of `dynamic`, you can use `object`. Instead of `string?`, you can use `string`.

You can also use the `typeof` operator with unbound generic types. The name of an unbound generic type must contain the appropriate number of commas, which is one less than the number of type parameters. The following example shows the usage of the `typeof` operator with an unbound generic type:

```

Console.WriteLine(typeof(Dictionary<, >));
// Output:
// System.Collections.Generic.Dictionary`2[TKey,TValue]

```

An expression can't be an argument of the `typeof` operator. To get the [System.Type](#) instance for the run-time type of an expression result, use the [Object.GetType](#) method.

Type testing with the `typeof` operator

Use the `typeof` operator to check if the run-time type of the expression result exactly matches a given type. The following example demonstrates the difference between type checking done with the `typeof` operator and the [is operator](#):

```

public class Animal { }

public class Giraffe : Animal { }

public static class TypeOfExample
{
    public static void Main()
    {
        object b = new Giraffe();
        Console.WriteLine(b is Animal); // output: True
        Console.WriteLine(b.GetType() == typeof(Animal)); // output: False

        Console.WriteLine(b is Giraffe); // output: True
        Console.WriteLine(b.GetType() == typeof(Giraffe)); // output: True
    }
}

```

Operator overloadability

The `is`, `as`, and `typeof` operators cannot be overloaded.

A user-defined type can't overload the `()` operator, but can define custom type conversions that can be performed by a cast expression. For more information, see [User-defined conversion operators](#).

C# language specification

For more information, see the following sections of the [C# language specification](#):

- [The is operator](#)
- [The as operator](#)
- [Cast expressions](#)
- [The typeof operator](#)

See also

- [C# reference](#)
- [C# operators and expressions](#)
- [How to safely cast by using pattern matching and the is and as operators](#)
- [Generics in .NET](#)

User-defined conversion operators (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

A user-defined type can define a custom implicit or explicit conversion from or to another type.

Implicit conversions don't require special syntax to be invoked and can occur in a variety of situations, for example, in assignments and methods invocations. Predefined C# implicit conversions always succeed and never throw an exception. User-defined implicit conversions should behave in that way as well. If a custom conversion can throw an exception or lose information, define it as an explicit conversion.

User-defined conversions are not considered by the `is` and `as` operators. Use a [cast expression](#) to invoke a user-defined explicit conversion.

Use the `operator` and `implicit` or `explicit` keywords to define an implicit or explicit conversion, respectively. The type that defines a conversion must be either a source type or a target type of that conversion. A conversion between two user-defined types can be defined in either of the two types.

The following example demonstrates how to define an implicit and explicit conversion:

```
using System;

public readonly struct Digit
{
    private readonly byte digit;

    public Digit(byte digit)
    {
        if (digit > 9)
        {
            throw new ArgumentOutOfRangeException(nameof(digit), "Digit cannot be greater than nine.");
        }
        this.digit = digit;
    }

    public static implicit operator byte(Digit d) => d.digit;
    public static explicit operator Digit(byte b) => new Digit(b);

    public override string ToString() => $"{digit}";
}

public static class UserDefinedConversions
{
    public static void Main()
    {
        var d = new Digit(7);

        byte number = d;
        Console.WriteLine(number); // output: 7

        Digit digit = (Digit)number;
        Console.WriteLine(digit); // output: 7
    }
}
```

You also use the `operator` keyword to overload a predefined C# operator. For more information, see [Operator overloading](#).

C# language specification

Pointer related operators (C# reference)

12/28/2021 • 7 minutes to read • [Edit Online](#)

You can use the following operators to work with pointers:

- Unary `&` ([address-of](#)) operator: to get the address of a variable
- Unary `*` ([pointer indirection](#)) operator: to obtain the variable pointed by a pointer
- The `->` ([member access](#)) and `[]` ([element access](#)) operators
- Arithmetic operators `+`, `-`, `++`, and `--`
- Comparison operators `==`, `!=`, `<`, `>`, `<=`, and `>=`

For information about pointer types, see [Pointer types](#).

NOTE

Any operation with pointers requires an [unsafe](#) context. The code that contains unsafe blocks must be compiled with the [AllowUnsafeBlocks](#) compiler option.

Address-of operator &

The unary `&` operator returns the address of its operand:

```
unsafe
{
    int number = 27;
    int* pointerToNumber = &number;

    Console.WriteLine($"Value of the variable: {number}");
    Console.WriteLine($"Address of the variable: {(long)pointerToNumber:X}");
}
// Output is similar to:
// Value of the variable: 27
// Address of the variable: 6C1457DBD4
```

The operand of the `&` operator must be a fixed variable. *Fixed* variables are variables that reside in storage locations that are unaffected by operation of the [garbage collector](#). In the preceding example, the local variable `number` is a fixed variable, because it resides on the stack. Variables that reside in storage locations that can be affected by the garbage collector (for example, relocated) are called *movable* variables. Object fields and array elements are examples of movable variables. You can get the address of a movable variable if you "fix", or "pin", it with a [fixed statement](#). The obtained address is valid only inside the block of a `fixed` statement. The following example shows how to use a `fixed` statement and the `&` operator:

```
unsafe
{
    byte[] bytes = { 1, 2, 3 };
    fixed (byte* pointerToFirst = &bytes[0])
    {
        // The address stored in pointerToFirst
        // is valid only inside this fixed statement block.
    }
}
```

You can't get the address of a constant or a value.

For more information about fixed and movable variables, see the [Fixed and moveable variables](#) section of the [C# language specification](#).

The binary `&` operator computes the [logical AND](#) of its Boolean operands or the [bitwise logical AND](#) of its integral operands.

Pointer indirection operator *

The unary pointer indirection operator `*` obtains the variable to which its operand points. It's also known as the dereference operator. The operand of the `*` operator must be of a pointer type.

```
unsafe
{
    char letter = 'A';
    char* pointerToLetter = &letter;
    Console.WriteLine($"Value of the `letter` variable: {letter}");
    Console.WriteLine($"Address of the `letter` variable: {(long)pointerToLetter:X}");

    *pointerToLetter = 'Z';
    Console.WriteLine($"Value of the `letter` variable after update: {letter}");
}
// Output is similar to:
// Value of the `letter` variable: A
// Address of the `letter` variable: DCB977DDF4
// Value of the `letter` variable after update: Z
```

You cannot apply the `*` operator to an expression of type `void*`.

The binary `*` operator computes the [product](#) of its numeric operands.

Pointer member access operator ->

The `->` operator combines [pointer indirection](#) and [member access](#). That is, if `x` is a pointer of type `T*` and `y` is an accessible member of type `T`, an expression of the form

```
x->y
```

is equivalent to

```
(*x).y
```

The following example demonstrates the usage of the `->` operator:

```

public struct Coords
{
    public int X;
    public int Y;
    public override string ToString() => $"({X}, {Y})";
}

public class PointerMemberAccessExample
{
    public static unsafe void Main()
    {
        Coords coords;
        Coords* p = &coords;
        p->X = 3;
        p->Y = 4;
        Console.WriteLine(p->ToString()); // output: (3, 4)
    }
}

```

You cannot apply the `->` operator to an expression of type `void*`.

Pointer element access operator `[]`

For an expression `p` of a pointer type, a pointer element access of the form `p[n]` is evaluated as `*(p + n)`, where `n` must be of a type implicitly convertible to `int`, `uint`, `long`, or `ulong`. For information about the behavior of the `+` operator with pointers, see the [Addition or subtraction of an integral value to or from a pointer](#) section.

The following example demonstrates how to access array elements with a pointer and the `[]` operator:

```

unsafe
{
    char* pointerToChars = stackalloc char[123];

    for (int i = 65; i < 123; i++)
    {
        pointerToChars[i] = (char)i;
    }

    Console.Write("Uppercase letters: ");
    for (int i = 65; i < 91; i++)
    {
        Console.Write(pointerToChars[i]);
    }
}
// Output:
// Uppercase letters: ABCDEFGHIJKLMNOPQRSTUVWXYZ

```

In the preceding example, a `stackalloc` expression allocates a block of memory on the stack.

NOTE

The pointer element access operator doesn't check for out-of-bounds errors.

You cannot use `[]` for pointer element access with an expression of type `void*`.

You can also use the `[]` operator for [array element or indexer access](#).

Pointer arithmetic operators

You can perform the following arithmetic operations with pointers:

- Add or subtract an integral value to or from a pointer
- Subtract two pointers
- Increment or decrement a pointer

You cannot perform those operations with pointers of type `void*`.

For information about supported arithmetic operations with numeric types, see [Arithmetic operators](#).

Addition or subtraction of an integral value to or from a pointer

For a pointer `p` of type `T*` and an expression `n` of a type implicitly convertible to `int`, `uint`, `long`, or `ulong`, addition and subtraction are defined as follows:

- Both `p + n` and `n + p` expressions produce a pointer of type `T*` that results from adding `n * sizeof(T)` to the address given by `p`.
- The `p - n` expression produces a pointer of type `T*` that results from subtracting `n * sizeof(T)` from the address given by `p`.

The `sizeof` operator obtains the size of a type in bytes.

The following example demonstrates the usage of the `+` operator with a pointer:

```
unsafe
{
    const int Count = 3;
    int[] numbers = new int[Count] { 10, 20, 30 };
    fixed (int* pointerToFirst = &numbers[0])
    {
        int* pointerToLast = pointerToFirst + (Count - 1);

        Console.WriteLine($"Value {pointerToFirst} at address {(long)pointerToFirst}");
        Console.WriteLine($"Value {pointerToLast} at address {(long)pointerToLast}");
    }
}
// Output is similar to:
// Value 10 at address 1818345918136
// Value 30 at address 1818345918144
```

Pointer subtraction

For two pointers `p1` and `p2` of type `T*`, the expression `p1 - p2` produces the difference between the addresses given by `p1` and `p2` divided by `sizeof(T)`. The type of the result is `long`. That is, `p1 - p2` is computed as `((long)(p1) - (long)(p2)) / sizeof(T)`.

The following example demonstrates the pointer subtraction:

```
unsafe
{
    int* numbers = stackalloc int[] { 0, 1, 2, 3, 4, 5 };
    int* p1 = &numbers[1];
    int* p2 = &numbers[5];
    Console.WriteLine(p2 - p1); // output: 4
}
```

Pointer increment and decrement

The `++` increment operator [adds](#) 1 to its pointer operand. The `--` decrement operator [subtracts](#) 1 from its pointer operand.

Both operators are supported in two forms: postfix (`p++` and `p--`) and prefix (`++p` and `--p`). The result of `p++` and `p--` is the value of `p` *before* the operation. The result of `++p` and `--p` is the value of `p` *after* the operation.

The following example demonstrates the behavior of both postfix and prefix increment operators:

```
unsafe
{
    int* numbers = stackalloc int[] { 0, 1, 2 };
    int* p1 = &numbers[0];
    int* p2 = p1;
    Console.WriteLine($"Before operation: p1 - {(long)p1}, p2 - {(long)p2}");
    Console.WriteLine($"Postfix increment of p1: {(long)(p1++)}");
    Console.WriteLine($"Prefix increment of p2: {(long)(++p2)}");
    Console.WriteLine($"After operation: p1 - {(long)p1}, p2 - {(long)p2}");
}
// Output is similar to
// Before operation: p1 - 816489946512, p2 - 816489946512
// Postfix increment of p1: 816489946512
// Prefix increment of p2: 816489946516
// After operation: p1 - 816489946516, p2 - 816489946516
```

Pointer comparison operators

You can use the `==`, `!=`, `<`, `>`, `<=`, and `>=` operators to compare operands of any pointer type, including `void*`. Those operators compare the addresses given by the two operands as if they were unsigned integers.

For information about the behavior of those operators for operands of other types, see the [Equality operators](#) and [Comparison operators](#) articles.

Operator precedence

The following list orders pointer related operators starting from the highest precedence to the lowest:

- Postfix increment `x++` and decrement `x--` operators and the `->` and `[]` operators
- Prefix increment `++x` and decrement `--x` operators and the `&` and `*` operators
- Additive `+` and `-` operators
- Comparison `<`, `>`, `<=`, and `>=` operators
- Equality `==` and `!=` operators

Use parentheses, `()`, to change the order of evaluation imposed by operator precedence.

For the complete list of C# operators ordered by precedence level, see the [Operator precedence](#) section of the [C# operators](#) article.

Operator overloadability

A user-defined type cannot overload the pointer related operators `&`, `*`, `->`, and `[]`.

Assignment operators (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The assignment operator `=` assigns the value of its right-hand operand to a variable, a [property](#), or an [indexer](#) element given by its left-hand operand. The result of an assignment expression is the value assigned to the left-hand operand. The type of the right-hand operand must be the same as the type of the left-hand operand or implicitly convertible to it.

The assignment operator `=` is right-associative, that is, an expression of the form

```
a = b = c
```

is evaluated as

```
a = (b = c)
```

The following example demonstrates the usage of the assignment operator with a local variable, a property, and an indexer element as its left-hand operand:

```
var numbers = new List<double>() { 1.0, 2.0, 3.0 };

Console.WriteLine(numbers.Capacity);
numbers.Capacity = 100;
Console.WriteLine(numbers.Capacity);
// Output:
// 4
// 100

int newFirstElement;
double originalFirstElement = numbers[0];
newFirstElement = 5;
numbers[0] = newFirstElement;
Console.WriteLine(originalFirstElement);
Console.WriteLine(numbers[0]);
// Output:
// 1
// 5
```

ref assignment operator

Beginning with C# 7.3, you can use the ref assignment operator `= ref` to reassign a [ref local](#) or [ref readonly local](#) variable. The following example demonstrates the usage of the ref assignment operator:

```

void Display(double[] s) => Console.WriteLine(string.Join(" ", s));

double[] arr = { 0.0, 0.0, 0.0 };
Display(arr);

ref double arrayElement = ref arr[0];
arrayElement = 3.0;
Display(arr);

arrayElement = ref arr[arr.Length - 1];
arrayElement = 5.0;
Display(arr);
// Output:
// 0 0 0
// 3 0 0
// 3 0 5

```

In the case of the ref assignment operator, both of its operands must be of the same type.

Compound assignment

For a binary operator `op`, a compound assignment expression of the form

```
x op= y
```

is equivalent to

```
x = x op y
```

except that `x` is only evaluated once.

Compound assignment is supported by [arithmetic](#), [Boolean logical](#), and [bitwise logical and shift](#) operators.

Null-coalescing assignment

Beginning with C# 8.0, you can use the null-coalescing assignment operator `??=` to assign the value of its right-hand operand to its left-hand operand only if the left-hand operand evaluates to `null`. For more information, see the [?? and ??= operators](#) article.

Operator overloadability

A user-defined type cannot [overload](#) the assignment operator. However, a user-defined type can define an implicit conversion to another type. That way, the value of a user-defined type can be assigned to a variable, a property, or an indexer element of another type. For more information, see [User-defined conversion operators](#).

A user-defined type cannot explicitly overload a compound assignment operator. However, if a user-defined type overloads a binary operator `op`, the `op=` operator, if it exists, is also implicitly overloaded.

C# language specification

For more information, see the [Assignment operators](#) section of the [C# language specification](#).

For more information about the ref assignment operator `= ref`, see the [feature proposal note](#).

Lambda expressions (C# reference)

12/28/2021 • 15 minutes to read • [Edit Online](#)

You use a *lambda expression* to create an anonymous function. Use the [lambda declaration operator](#) `=>` to separate the lambda's parameter list from its body. A lambda expression can be of any of the following two forms:

- [Expression lambda](#) that has an expression as its body:

```
(input-parameters) => expression
```

- [Statement lambda](#) that has a statement block as its body:

```
(input-parameters) => { <sequence-of-statements> }
```

To create a lambda expression, you specify input parameters (if any) on the left side of the lambda operator and an expression or a statement block on the other side.

Any lambda expression can be converted to a [delegate](#) type. The delegate type to which a lambda expression can be converted is defined by the types of its parameters and return value. If a lambda expression doesn't return a value, it can be converted to one of the `Action` delegate types; otherwise, it can be converted to one of the `Func` delegate types. For example, a lambda expression that has two parameters and returns no value can be converted to an `Action<T1,T2>` delegate. A lambda expression that has one parameter and returns a value can be converted to a `Func<T,TResult>` delegate. In the following example, the lambda expression `x => x * x`, which specifies a parameter that's named `x` and returns the value of `x` squared, is assigned to a variable of a delegate type:

```
Func<int, int> square = x => x * x;  
Console.WriteLine(square(5));  
// Output:  
// 25
```

Expression lambdas can also be converted to the [expression tree](#) types, as the following example shows:

```
System.Linq.Expressions.Expression<Func<int, int>> e = x => x * x;  
Console.WriteLine(e);  
// Output:  
// x => (x * x)
```

You can use lambda expressions in any code that requires instances of delegate types or expression trees, for example as an argument to the [Task.Run\(Action\)](#) method to pass the code that should be executed in the background. You can also use lambda expressions when you write [LINQ in C#](#), as the following example shows:

```
int[] numbers = { 2, 3, 4, 5 };  
var squaredNumbers = numbers.Select(x => x * x);  
Console.WriteLine(string.Join(" ", squaredNumbers));  
// Output:  
// 4 9 16 25
```

When you use method-based syntax to call the [Enumerable.Select](#) method in the [System.Linq.Enumerable](#) class, for example in LINQ to Objects and LINQ to XML, the parameter is a delegate type [System.Func<T, TResult>](#). When you call the [Queryable.Select](#) method in the [System.Linq.Queryable](#) class, for example in LINQ to SQL, the parameter type is an expression tree type [Expression<Func<TSource, TResult>>](#). In both cases, you can use the same lambda expression to specify the parameter value. That makes the two `Select` calls to look similar although in fact the type of objects created from the lambdas is different.

Expression lambdas

A lambda expression with an expression on the right side of the `=>` operator is called an *expression lambda*. An expression lambda returns the result of the expression and takes the following basic form:

```
(input-parameters) => expression
```

The body of an expression lambda can consist of a method call. However, if you're creating [expression trees](#) that are evaluated outside the context of the .NET Common Language Runtime (CLR), such as in SQL Server, you shouldn't use method calls in lambda expressions. The methods will have no meaning outside the context of the .NET Common Language Runtime (CLR).

Statement lambdas

A statement lambda resembles an expression lambda except that its statements are enclosed in braces:

```
(input-parameters) => { <sequence-of-statements> }
```

The body of a statement lambda can consist of any number of statements; however, in practice there are typically no more than two or three.

```
Action<string> greet = name =>
{
    string greeting = $"Hello {name}!";
    Console.WriteLine(greeting);
};
greet("World");
// Output:
// Hello World!
```

You can't use statement lambdas to create expression trees.

Input parameters of a lambda expression

You enclose input parameters of a lambda expression in parentheses. Specify zero input parameters with empty parentheses:

```
Action line = () => Console.WriteLine();
```

If a lambda expression has only one input parameter, parentheses are optional:

```
Func<double, double> cube = x => x * x * x;
```

Two or more input parameters are separated by commas:

```
Func<int, int, bool> testForEquality = (x, y) => x == y;
```

Sometimes the compiler can't infer the types of input parameters. You can specify the types explicitly as shown in the following example:

```
Func<int, string, bool> isTooLong = (int x, string s) => s.Length > x;
```

Input parameter types must be all explicit or all implicit; otherwise, a [CS0748](#) compiler error occurs.

Beginning with C# 9.0, you can use [discards](#) to specify two or more input parameters of a lambda expression that aren't used in the expression:

```
Func<int, int, int> constant = (_, _) => 42;
```

Lambda discard parameters may be useful when you use a lambda expression to [provide an event handler](#).

NOTE

For backwards compatibility, if only a single input parameter is named `_`, then, within a lambda expression, `_` is treated as the name of that parameter.

Async lambdas

You can easily create lambda expressions and statements that incorporate asynchronous processing by using the [async](#) and [await](#) keywords. For example, the following Windows Forms example contains an event handler that calls and awaits an async method, `ExampleMethodAsync`.

```
public partial class Form1 : Form
{
    public Form1()
    {
        InitializeComponent();
        button1.Click += button1_Click;
    }

    private async void button1_Click(object sender, EventArgs e)
    {
        await ExampleMethodAsync();
        textBox1.Text += "\r\nControl returned to Click event handler.\n";
    }

    private async Task ExampleMethodAsync()
    {
        // The following line simulates a task-returning asynchronous process.
        await Task.Delay(1000);
    }
}
```

You can add the same event handler by using an async lambda. To add this handler, add an `async` modifier before the lambda parameter list, as the following example shows:

```

public partial class Form1 : Form
{
    public Form1()
    {
        InitializeComponent();
        button1.Click += async (sender, e) =>
        {
            await ExampleMethodAsync();
            textBox1.Text += "\r\nControl returned to Click event handler.\n";
        };
    }

    private async Task ExampleMethodAsync()
    {
        // The following line simulates a task-returning asynchronous process.
        await Task.Delay(1000);
    }
}

```

For more information about how to create and use async methods, see [Asynchronous Programming with async and await](#).

Lambda expressions and tuples

Starting with C# 7.0, the C# language provides built-in support for [tuples](#). You can provide a tuple as an argument to a lambda expression, and your lambda expression can also return a tuple. In some cases, the C# compiler uses type inference to determine the types of tuple components.

You define a tuple by enclosing a comma-delimited list of its components in parentheses. The following example uses tuple with three components to pass a sequence of numbers to a lambda expression, which doubles each value and returns a tuple with three components that contains the result of the multiplications.

```

Func<(int, int, int), (int, int, int)> doubleThem = ns => (2 * ns.Item1, 2 * ns.Item2, 2 * ns.Item3);
var numbers = (2, 3, 4);
var doubledNumbers = doubleThem(numbers);
Console.WriteLine($"The set {numbers} doubled: {doubledNumbers}");
// Output:
// The set (2, 3, 4) doubled: (4, 6, 8)

```

Ordinarily, the fields of a tuple are named `Item1`, `Item2`, and so on. You can, however, define a tuple with named components, as the following example does.

```

Func<(int n1, int n2, int n3), (int, int, int)> doubleThem = ns => (2 * ns.n1, 2 * ns.n2, 2 * ns.n3);
var numbers = (2, 3, 4);
var doubledNumbers = doubleThem(numbers);
Console.WriteLine($"The set {numbers} doubled: {doubledNumbers}");

```

For more information about C# tuples, see [Tuple types](#).

Lambdas with the standard query operators

LINQ to Objects, among other implementations, have an input parameter whose type is one of the `Func<TResult>` family of generic delegates. These delegates use type parameters to define the number and type of input parameters, and the return type of the delegate. `Func` delegates are useful for encapsulating user-defined expressions that are applied to each element in a set of source data. For example, consider the `Func<T,TResult>` delegate type:

```
public delegate TResult Func<in T, out TResult>(T arg)
```

The delegate can be instantiated as a `Func<int, bool>` instance where `int` is an input parameter and `bool` is the return value. The return value is always specified in the last type parameter. For example, `Func<int, string, bool>` defines a delegate with two input parameters, `int` and `string`, and a return type of `bool`. The following `Func` delegate, when it's invoked, returns Boolean value that indicates whether the input parameter is equal to five:

```
Func<int, bool> equalsFive = x => x == 5;
bool result = equalsFive(4);
Console.WriteLine(result);    // False
```

You can also supply a lambda expression when the argument type is an [Expression<TDelegate>](#), for example in the standard query operators that are defined in the [Queryable](#) type. When you specify an [Expression<TDelegate>](#) argument, the lambda is compiled to an expression tree.

The following example uses the [Count](#) standard query operator:

```
int[] numbers = { 5, 4, 1, 3, 9, 8, 6, 7, 2, 0 };
int oddNumbers = numbers.Count(n => n % 2 == 1);
Console.WriteLine($"There are {oddNumbers} odd numbers in {string.Join(" ", numbers)}");
```

The compiler can infer the type of the input parameter, or you can also specify it explicitly. This particular lambda expression counts those integers (`n`) which when divided by two have a remainder of 1.

The following example produces a sequence that contains all elements in the `numbers` array that precede the 9, because that's the first number in the sequence that doesn't meet the condition:

```
int[] numbers = { 5, 4, 1, 3, 9, 8, 6, 7, 2, 0 };
var firstNumbersLessThanSix = numbers.TakeWhile(n => n < 6);
Console.WriteLine(string.Join(" ", firstNumbersLessThanSix));
// Output:
// 5 4 1 3
```

The following example specifies multiple input parameters by enclosing them in parentheses. The method returns all the elements in the `numbers` array until it finds a number whose value is less than its ordinal position in the array:

```
int[] numbers = { 5, 4, 1, 3, 9, 8, 6, 7, 2, 0 };
var firstSmallNumbers = numbers.TakeWhile((n, index) => n >= index);
Console.WriteLine(string.Join(" ", firstSmallNumbers));
// Output:
// 5 4
```

You don't use lambda expressions directly in [query expressions](#), but you can use them in method calls within query expressions, as the following example shows:

```

var numberSets = new List<int[]>
{
    new[] { 1, 2, 3, 4, 5 },
    new[] { 0, 0, 0 },
    new[] { 9, 8 },
    new[] { 1, 0, 1, 0, 1, 0, 1, 0 }
};

var setsWithManyPositives =
    from numberSet in numberSets
    where numberSet.Count(n => n > 0) > 3
    select numberSet;

foreach (var numberSet in setsWithManyPositives)
{
    Console.WriteLine(string.Join(" ", numberSet));
}
// Output:
// 1 2 3 4 5
// 1 0 1 0 1 0 1 0

```

Type inference in lambda expressions

When writing lambdas, you often don't have to specify a type for the input parameters because the compiler can infer the type based on the lambda body, the parameter types, and other factors as described in the C# language specification. For most of the standard query operators, the first input is the type of the elements in the source sequence. If you're querying an `IEnumerable<Customer>`, then the input variable is inferred to be a `Customer` object, which means you have access to its methods and properties:

```
customers.Where(c => c.City == "London");
```

The general rules for type inference for lambdas are as follows:

- The lambda must contain the same number of parameters as the delegate type.
- Each input parameter in the lambda must be implicitly convertible to its corresponding delegate parameter.
- The return value of the lambda (if any) must be implicitly convertible to the delegate's return type.

Natural type of a lambda expression

A lambda expression in itself doesn't have a type because the common type system has no intrinsic concept of "lambda expression." However, it's sometimes convenient to speak informally of the "type" of a lambda expression. That informal "type" refers to the delegate type or [Expression](#) type to which the lambda expression is converted.

Beginning with C# 10, a lambda expression may have a *natural type*. Instead of forcing you to declare a delegate type, such as `Func<...>` or `Action<...>` for a lambda expression, the compiler may infer the delegate type from the lambda expression. For example, consider the following declaration:

```
var parse = (string s) => int.Parse(s);
```

The compiler can infer `parse` to be a `Func<string, int>`. The compiler chooses an available `Func` or `Action` delegate, if a suitable one exists. Otherwise, it synthesizes a delegate type. For example, the delegate type is synthesized if the lambda expression has `ref` parameters. When a lambda expression has a natural type, it can be assigned to a less explicit type, such as `System.Object` or `System.Delegate`:

```
object parse = (string s) => int.Parse(s); // Func<string, int>
Delegate parse = (string s) => int.Parse(s); // Func<string, int>
```

Method groups (that is, method names without parameter lists) with exactly one overload have a natural type:

```
var read = Console.Read; // Just one overload; Func<int> inferred
var write = Console.Write; // ERROR: Multiple overloads, can't choose
```

If you assign a lambda expression to [System.Linq.Expressions.LambdaExpression](#), or [System.Linq.Expressions.Expression](#), and the lambda has a natural delegate type, the expression has a natural type of [System.Linq.Expressions.Expression<TDelegate>](#), with the natural delegate type used as the argument for the type parameter:

```
LambdaExpression parseExpr = (string s) => int.Parse(s); // Expression<Func<string, int>>
Expression parseExpr = (string s) => int.Parse(s); // Expression<Func<string, int>>
```

Not all lambda expressions have a natural type. Consider the following declaration:

```
var parse = s => int.Parse(s); // ERROR: Not enough type info in the lambda
```

The compiler can't infer a parameter type for `s`. When the compiler can't infer a natural type, you must declare the type:

```
Func<string, int> parse = s => int.Parse(s);
```

Explicit return type

Typically, the return type of a lambda expression is obvious and inferred. For some expressions, that doesn't work:

```
var choose = (bool b) => b ? 1 : "two"; // ERROR: Can't infer return type
```

Beginning with C# 10, you can specify the return type of a lambda expression before the input parameters. When you specify an explicit return type, you must parenthesize the input parameters:

```
var choose = object (bool b) => b ? 1 : "two"; // Func<bool, object>
```

Attributes

Beginning with C# 10, you can add attributes to a lambda expression and its parameters. The following example shows how to add attributes to a lambda expression:

```
Func<string, int> parse = [Example(1)] (s) => int.Parse(s);
var choose = [Example(2)][Example(3)] object (bool b) => b ? 1 : "two";
```

You can also add attributes to the input parameters or return value, as the following example shows:

```
var sum = ([Example(1)] int a, [Example(2), Example(3)] int b) => a + b;  
var inc = [return: Example(1)] (int s) => s++;
```

As the preceding examples show, you must parenthesize the input parameters when you add attributes to a lambda expression or its parameters.

IMPORTANT

Lambda expressions are invoked through the underlying delegate type. That is different than methods and local functions. The delegate's `Invoke` method doesn't check attributes on the lambda expression. Attributes don't have any effect when the lambda expression is invoked. Attributes on lambda expressions are useful for code analysis, and can be discovered via reflection. One consequence of this decision is that the `System.Diagnostics.ConditionalAttribute` cannot be applied to a lambda expression.

Capture of outer variables and variable scope in lambda expressions

Lambdas can refer to *outer variables*. These are the variables that are in scope in the method that defines the lambda expression, or in scope in the type that contains the lambda expression. Variables that are captured in this manner are stored for use in the lambda expression even if the variables would otherwise go out of scope and be garbage collected. An outer variable must be definitely assigned before it can be consumed in a lambda expression. The following example demonstrates these rules:

```

public static class VariableScopeWithLambdas
{
    public class VariableCaptureGame
    {
        internal Action<int> updateCapturedLocalVariable;
        internal Func<int, bool> isEqualToCapturedLocalVariable;

        public void Run(int input)
        {
            int j = 0;

            updateCapturedLocalVariable = x =>
            {
                j = x;
                bool result = j > input;
                Console.WriteLine($"{j} is greater than {input}: {result}");
            };

            isEqualToCapturedLocalVariable = x => x == j;

            Console.WriteLine($"Local variable before lambda invocation: {j}");
            updateCapturedLocalVariable(10);
            Console.WriteLine($"Local variable after lambda invocation: {j}");
        }
    }

    public static void Main()
    {
        var game = new VariableCaptureGame();

        int gameInput = 5;
        game.Run(gameInput);

        int jTry = 10;
        bool result = game.isEqualToCapturedLocalVariable(jTry);
        Console.WriteLine($"Captured local variable is equal to {jTry}: {result}");

        int anotherJ = 3;
        game.updateCapturedLocalVariable(anotherJ);

        bool equalToAnother = game.isEqualToCapturedLocalVariable(anotherJ);
        Console.WriteLine($"Another lambda observes a new value of captured variable: {equalToAnother}");
    }
    // Output:
    // Local variable before lambda invocation: 0
    // 10 is greater than 5: True
    // Local variable after lambda invocation: 10
    // Captured local variable is equal to 10: True
    // 3 is greater than 5: False
    // Another lambda observes a new value of captured variable: True
}

```

The following rules apply to variable scope in lambda expressions:

- A variable that is captured won't be garbage-collected until the delegate that references it becomes eligible for garbage collection.
- Variables introduced within a lambda expression aren't visible in the enclosing method.
- A lambda expression can't directly capture an [in](#), [ref](#), or [out](#) parameter from the enclosing method.
- A [return](#) statement in a lambda expression doesn't cause the enclosing method to return.
- A lambda expression can't contain a [goto](#), [break](#), or [continue](#) statement if the target of that jump statement is outside the lambda expression block. It's also an error to have a jump statement outside the lambda expression block if the target is inside the block.

Beginning with C# 9.0, you can apply the `static` modifier to a lambda expression to prevent unintentional capture of local variables or instance state by the lambda:

```
Func<double, double> square = static x => x * x;
```

A static lambda can't capture local variables or instance state from enclosing scopes, but may reference static members and constant definitions.

C# language specification

For more information, see the [Anonymous function expressions](#) section of the [C# language specification](#).

Patterns (C# reference)

12/28/2021 • 14 minutes to read • [Edit Online](#)

C# introduced pattern matching in C# 7.0. Since then, each major C# version extends pattern matching capabilities. The following C# expressions and statements support pattern matching:

- `is` [expression](#)
- `switch` [statement](#)
- `switch` [expression](#) (introduced in C# 8.0)

In those constructs, you can match an input expression against any of the following patterns:

- [Declaration pattern](#): to check the run-time type of an expression and, if a match succeeds, assign an expression result to a declared variable. Introduced in C# 7.0.
- [Type pattern](#): to check the run-time type of an expression. Introduced in C# 9.0.
- [Constant pattern](#): to test if an expression result equals a specified constant. Introduced in C# 7.0.
- [Relational patterns](#): to compare an expression result with a specified constant. Introduced in C# 9.0.
- [Logical patterns](#): to test if an expression matches a logical combination of patterns. Introduced in C# 9.0.
- [Property pattern](#): to test if an expression's properties or fields match nested patterns. Introduced in C# 8.0.
- [Positional pattern](#): to deconstruct an expression result and test if the resulting values match nested patterns. Introduced in C# 8.0.
- `var` [pattern](#): to match any expression and assign its result to a declared variable. Introduced in C# 7.0.
- [Discard pattern](#): to match any expression. Introduced in C# 8.0.

[Logical](#), [property](#), and [positional](#) patterns are *recursive* patterns. That is, they can contain *nested* patterns.

For the example of how to use those patterns to build a data-driven algorithm, see [Tutorial: Use pattern matching to build type-driven and data-driven algorithms](#).

Declaration and type patterns

You use declaration and type patterns to check if the run-time type of an expression is compatible with a given type. With a declaration pattern, you can also declare a new local variable. When a declaration pattern matches an expression, that variable is assigned a converted expression result, as the following example shows:

```
object greeting = "Hello, World!";
if (greeting is string message)
{
    Console.WriteLine(message.ToLower()); // output: hello, world!
}
```

Beginning with C# 7.0, a *declaration pattern* with type `T` matches an expression when an expression result is non-null and any of the following conditions are true:

- The run-time type of an expression result is `T`.
- The run-time type of an expression result derives from type `T`, implements interface `T`, or another [implicit reference conversion](#) exists from it to `T`. The following example demonstrates two cases when this condition is true:

```

var numbers = new int[] { 10, 20, 30 };
Console.WriteLine(GetSourceLabel(numbers)); // output: 1

var letters = new List<char> { 'a', 'b', 'c', 'd' };
Console.WriteLine(GetSourceLabel(letters)); // output: 2

static int GetSourceLabel<T>(IEnumerable<T> source) => source switch
{
    Array array => 1,
    ICollection<T> collection => 2,
    _ => 3,
};

```

In the preceding example, at the first call to the `GetSourceLabel` method, the first pattern matches an argument value because the argument's run-time type `int[]` derives from the `Array` type. At the second call to the `GetSourceLabel` method, the argument's run-time type `List<T>` doesn't derive from the `Array` type but implements the `ICollection<T>` interface.

- The run-time type of an expression result is a [nullable value type](#) with the underlying type `T`.
- A [boxing](#) or [unboxing](#) conversion exists from the run-time type of an expression result to type `T`.

The following example demonstrates the last two conditions:

```

int? xNullable = 7;
int y = 23;
object yBoxed = y;
if (xNullable is int a && yBoxed is int b)
{
    Console.WriteLine(a + b); // output: 30
}

```

If you want to check only the type of an expression, you can use a discard `_` in place of a variable's name, as the following example shows:

```

public abstract class Vehicle {}
public class Car : Vehicle {}
public class Truck : Vehicle {}

public static class TollCalculator
{
    public static decimal CalculateToll(this Vehicle vehicle) => vehicle switch
    {
        Car _ => 2.00m,
        Truck _ => 7.50m,
        null => throw new ArgumentNullException(nameof(vehicle)),
        _ => throw new ArgumentException("Unknown type of a vehicle", nameof(vehicle)),
    };
}

```

Beginning with C# 9.0, for that purpose you can use a *type pattern*, as the following example shows:

```

public static decimal CalculateToll(this Vehicle vehicle) => vehicle switch
{
    Car => 2.00m,
    Truck => 7.50m,
    null => throw new ArgumentNullException(nameof(vehicle)),
    _ => throw new ArgumentException("Unknown type of a vehicle", nameof(vehicle)),
};

```

Like a declaration pattern, a type pattern matches an expression when an expression result is non-null and its run-time type satisfies any of the conditions listed above.

For more information, see the [Declaration pattern](#) and [Type pattern](#) sections of the feature proposal notes.

Constant pattern

Beginning with C# 7.0, you use a *constant pattern* to test if an expression result equals a specified constant, as the following example shows:

```
public static decimal GetGroupTicketPrice(int visitorCount) => visitorCount switch
{
    1 => 12.0m,
    2 => 20.0m,
    3 => 27.0m,
    4 => 32.0m,
    0 => 0.0m,
    _ => throw new ArgumentException($"Not supported number of visitors: {visitorCount}",
    nameof(visitorCount)),
};
```

In a constant pattern, you can use any constant expression, such as:

- an [integer](#) or [floating-point](#) numerical literal
- a [char](#) or a [string](#) literal
- a Boolean value `true` or `false`
- an [enum](#) value
- the name of a declared [const](#) field or local
- `null`

Use a constant pattern to check for `null`, as the following example shows:

```
if (input is null)
{
    return;
}
```

The compiler guarantees that no user-overloaded equality operator `==` is invoked when expression `x is null` is evaluated.

Beginning with C# 9.0, you can use a [negated](#) `null` constant pattern to check for non-null, as the following example shows:

```
if (input is not null)
{
    // ...
}
```

For more information, see the [Constant pattern](#) section of the feature proposal note.

Relational patterns

Beginning with C# 9.0, you use a *relational pattern* to compare an expression result with a constant, as the following example shows:

```

Console.WriteLine(Classify(13)); // output: Too high
Console.WriteLine(Classify(double.NaN)); // output: Unknown
Console.WriteLine(Classify(2.4)); // output: Acceptable

static string Classify(double measurement) => measurement switch
{
    < -4.0 => "Too low",
    > 10.0 => "Too high",
    double.NaN => "Unknown",
    _ => "Acceptable",
};

```

In a relational pattern, you can use any of the [relational operators](#) `<`, `>`, `<=`, or `>=`. The right-hand part of a relational pattern must be a constant expression. The constant expression can be of an [integer](#), [floating-point](#), [char](#), or [enum](#) type.

To check if an expression result is in a certain range, match it against a [conjunctive](#) `and` pattern, as the following example shows:

```

Console.WriteLine(GetCalendarSeason(new DateTime(2021, 3, 14))); // output: spring
Console.WriteLine(GetCalendarSeason(new DateTime(2021, 7, 19))); // output: summer
Console.WriteLine(GetCalendarSeason(new DateTime(2021, 2, 17))); // output: winter

static string GetCalendarSeason(DateTime date) => date.Month switch
{
    >= 3 and < 6 => "spring",
    >= 6 and < 9 => "summer",
    >= 9 and < 12 => "autumn",
    12 or (>= 1 and < 3) => "winter",
    _ => throw new ArgumentOutOfRangeException(nameof(date), $"Date with unexpected month: {date.Month}."),
};

```

If an expression result is `null` or fails to convert to the type of a constant by a nullable or unboxing conversion, a relational pattern doesn't match an expression.

For more information, see the [Relational patterns](#) section of the feature proposal note.

Logical patterns

Beginning with C# 9.0, you use the `not`, `and`, and `or` pattern combinators to create the following *logical patterns*:

- *Negation* `not` pattern that matches an expression when the negated pattern doesn't match the expression. The following example shows how you can negate a [constant](#) `null` pattern to check if an expression is non-null:

```

if (input is not null)
{
    // ...
}

```

- *Conjunctive* `and` pattern that matches an expression when both patterns match the expression. The following example shows how you can combine [relational patterns](#) to check if a value is in a certain range:

```

Console.WriteLine(Classify(13)); // output: High
Console.WriteLine(Classify(-100)); // output: Too low
Console.WriteLine(Classify(5.7)); // output: Acceptable

static string Classify(double measurement) => measurement switch
{
    < -40.0 => "Too low",
    >= -40.0 and < 0 => "Low",
    >= 0 and < 10.0 => "Acceptable",
    >= 10.0 and < 20.0 => "High",
    >= 20.0 => "Too high",
    double.NaN => "Unknown",
};

```

- *Disjunctive* `or` pattern that matches an expression when either of patterns matches the expression, as the following example shows:

```

Console.WriteLine(GetCalendarSeason(new DateTime(2021, 1, 19))); // output: winter
Console.WriteLine(GetCalendarSeason(new DateTime(2021, 10, 9))); // output: autumn
Console.WriteLine(GetCalendarSeason(new DateTime(2021, 5, 11))); // output: spring

static string GetCalendarSeason(DateTime date) => date.Month switch
{
    3 or 4 or 5 => "spring",
    6 or 7 or 8 => "summer",
    9 or 10 or 11 => "autumn",
    12 or 1 or 2 => "winter",
    _ => throw new ArgumentOutOfRangeException(nameof(date), $"Date with unexpected month: {date.Month}."),
};

```

As the preceding example shows, you can repeatedly use the pattern combinators in a pattern.

Precedence and order of checking

The following list orders pattern combinators starting from the highest precedence to the lowest:

- `not`
- `and`
- `or`

To explicitly specify the precedence, use parentheses, as the following example shows:

```

static bool IsLetter(char c) => c is (>= 'a' and <= 'z') or (>= 'A' and <= 'Z');

```

NOTE

The order in which patterns are checked is undefined. At run time, the right-hand nested patterns of `or` and `and` patterns can be checked first.

For more information, see the [Pattern combinators](#) section of the feature proposal note.

Property pattern

Beginning with C# 8.0, you use a *property pattern* to match an expression's properties or fields against nested patterns, as the following example shows:

```
static bool IsConferenceDay(DateTime date) => date is { Year: 2020, Month: 5, Day: 19 or 20 or 21 };
```

A property pattern matches an expression when an expression result is non-null and every nested pattern matches the corresponding property or field of the expression result.

You can also add a run-time type check and a variable declaration to a property pattern, as the following example shows:

```
Console.WriteLine(TakeFive("Hello, world!")); // output: Hello
Console.WriteLine(TakeFive("Hi!")); // output: Hi!
Console.WriteLine(TakeFive(new[] { '1', '2', '3', '4', '5', '6', '7' })); // output: 12345
Console.WriteLine(TakeFive(new[] { 'a', 'b', 'c' })); // output: abc

static string TakeFive(object input) => input switch
{
    string { Length: >= 5 } s => s.Substring(0, 5),
    string s => s,

    ICollection<char> { Count: >= 5 } symbols => new string(symbols.Take(5).ToArray()),
    ICollection<char> symbols => new string(symbols.ToArray()),

    null => throw new ArgumentNullException(nameof(input)),
    _ => throw new ArgumentException("Not supported input type."),
};
```

A property pattern is a recursive pattern. That is, you can use any pattern as a nested pattern. Use a property pattern to match parts of data against nested patterns, as the following example shows:

```
public record Point(int X, int Y);
public record Segment(Point Start, Point End);

static bool IsAnyEndOnXAxis(Segment segment) =>
    segment is { Start: { Y: 0 } } or { End: { Y: 0 } };
```

The preceding example uses two features available in C# 9.0 and later: `or` [pattern combinator](#) and [record types](#).

Beginning with C# 10, you can reference nested properties or fields within a property pattern. For example, you can refactor the method from the preceding example into the following equivalent code:

```
static bool IsAnyEndOnXAxis(Segment segment) =>
    segment is { Start.Y: 0 } or { End.Y: 0 };
```

For more information, see the [Property pattern](#) section of the feature proposal note and the [Extended property patterns](#) feature proposal note.

Positional pattern

Beginning with C# 8.0, you use a *positional pattern* to deconstruct an expression result and match the resulting values against the corresponding nested patterns, as the following example shows:

```

public readonly struct Point
{
    public int X { get; }
    public int Y { get; }

    public Point(int x, int y) => (X, Y) = (x, y);

    public void Deconstruct(out int x, out int y) => (x, y) = (X, Y);
}

static string Classify(Point point) => point switch
{
    (0, 0) => "Origin",
    (1, 0) => "positive X basis end",
    (0, 1) => "positive Y basis end",
    _ => "Just a point",
};

```

At the preceding example, the type of an expression contains the [Deconstruct](#) method, which is used to deconstruct an expression result. You can also match expressions of [tuple types](#) against positional patterns. In that way, you can match multiple inputs against various patterns, as the following example shows:

```

static decimal GetGroupTicketPriceDiscount(int groupSize, DateTime visitDate)
=> (groupSize, visitDate.DayOfWeek) switch
{
    (<= 0, _) => throw new ArgumentException("Group size must be positive."),
    (_, DayOfWeek.Saturday or DayOfWeek.Sunday) => 0.0m,
    (>= 5 and < 10, DayOfWeek.Monday) => 20.0m,
    (>= 10, DayOfWeek.Monday) => 30.0m,
    (>= 5 and < 10, _) => 12.0m,
    (>= 10, _) => 15.0m,
    _ => 0.0m,
};

```

The preceding example uses [relational](#) and [logical](#) patterns, which are available in C# 9.0 and later.

You can use the names of tuple elements and `Deconstruct` parameters in a positional pattern, as the following example shows:

```

var numbers = new List<int> { 1, 2, 3 };
if (SumAndCount(numbers) is (Sum: var sum, Count: > 0))
{
    Console.WriteLine($"Sum of [{string.Join(" ", numbers)}] is {sum}"); // output: Sum of [1 2 3] is 6
}

static (double Sum, int Count) SumAndCount(IEnumerable<int> numbers)
{
    int sum = 0;
    int count = 0;
    foreach (int number in numbers)
    {
        sum += number;
        count++;
    }
    return (sum, count);
}

```

You can also extend a positional pattern in any of the following ways:

- Add a run-time type check and a variable declaration, as the following example shows:

```

public record Point2D(int X, int Y);
public record Point3D(int X, int Y, int Z);

static string PrintIfAllCoordinatesArePositive(object point) => point switch
{
    Point2D (> 0, > 0) p => p.ToString(),
    Point3D (> 0, > 0, > 0) p => p.ToString(),
    _ => string.Empty,
};

```

The preceding example uses [positional records](#) that implicitly provide the `Deconstruct` method.

- Use a [property pattern](#) within a positional pattern, as the following example shows:

```

public record WeightedPoint(int X, int Y)
{
    public double Weight { get; set; }
}

static bool IsInDomain(WeightedPoint point) => point is (>= 0, >= 0) { Weight: >= 0.0 };

```

- Combine two preceding usages, as the following example shows:

```

if (input is WeightedPoint (> 0, > 0) { Weight: > 0.0 } p)
{
    // ..
}

```

A positional pattern is a recursive pattern. That is, you can use any pattern as a nested pattern.

For more information, see the [Positional pattern](#) section of the feature proposal note.

var pattern

Beginning with C# 7.0, you use a `var` *pattern* to match any expression, including `null`, and assign its result to a new local variable, as the following example shows:

```

static bool IsAcceptable(int id, int absLimit) =>
    SimulateDataFetch(id) is var results
    && results.Min() >= -absLimit
    && results.Max() <= absLimit;

static int[] SimulateDataFetch(int id)
{
    var rand = new Random();
    return Enumerable
        .Range(start: 0, count: 5)
        .Select(s => rand.Next(minValue: -10, maxValue: 11))
        .ToArray();
}

```

A `var` pattern is useful when you need a temporary variable within a Boolean expression to hold the result of intermediate calculations. You can also use a `var` pattern when you need to perform additional checks in `when` case guards of a `switch` expression or statement, as the following example shows:

```
public record Point(int X, int Y);

static Point Transform(Point point) => point switch
{
    var (x, y) when x < y => new Point(-x, y),
    var (x, y) when x > y => new Point(x, -y),
    var (x, y) => new Point(x, y),
};

static void TestTransform()
{
    Console.WriteLine(Transform(new Point(1, 2))); // output: Point { X = -1, Y = 2 }
    Console.WriteLine(Transform(new Point(5, 2))); // output: Point { X = 5, Y = -2 }
}
```

In the preceding example, pattern `var (x, y)` is equivalent to a [positional pattern](#) `(var x, var y)`.

In a `var` pattern, the type of a declared variable is the compile-time type of the expression that is matched against the pattern.

For more information, see the [Var pattern](#) section of the feature proposal note.

Discard pattern

Beginning with C# 8.0, you use a *discard pattern* `_` to match any expression, including `null`, as the following example shows:

```
Console.WriteLine(GetDiscountInPercent(DayOfWeek.Friday)); // output: 5.0
Console.WriteLine(GetDiscountInPercent(null)); // output: 0.0
Console.WriteLine(GetDiscountInPercent((DayOfWeek)10)); // output: 0.0

static decimal GetDiscountInPercent(DayOfWeek? dayOfWeek) => dayOfWeek switch
{
    DayOfWeek.Monday => 0.5m,
    DayOfWeek.Tuesday => 12.5m,
    DayOfWeek.Wednesday => 7.5m,
    DayOfWeek.Thursday => 12.5m,
    DayOfWeek.Friday => 5.0m,
    DayOfWeek.Saturday => 2.5m,
    DayOfWeek.Sunday => 2.0m,
    _ => 0.0m,
};
```

In the preceding example, a discard pattern is used to handle `null` and any integer value that doesn't have the corresponding member of the [DayOfWeek](#) enumeration. That guarantees that a `switch` expression in the example handles all possible input values. If you don't use a discard pattern in a `switch` expression and none of the expression's patterns matches an input, the runtime [throws an exception](#). The compiler generates a warning if a `switch` expression doesn't handle all possible input values.

A discard pattern cannot be a pattern in an `is` expression or a `switch` statement. In those cases, to match any expression, use a [var pattern](#) with a discard: `var _`.

For more information, see the [Discard pattern](#) section of the feature proposal note.

Parenthesized pattern

Beginning with C# 9.0, you can put parentheses around any pattern. Typically, you do that to emphasize or change the precedence in [logical patterns](#), as the following example shows:

```
if (input is not (float or double))
{
    return;
}
```

C# language specification

For more information, see the following feature proposal notes:

- [Pattern matching for C# 7.0](#)
- [Recursive pattern matching \(introduced in C# 8.0\)](#)
- [Pattern-matching changes for C# 9.0](#)
- [Extended property patterns \(C# 10\)](#)

See also

- [C# operators and expressions](#)
- [Tutorial: Use pattern matching to build type-driven and data-driven algorithms](#)

+ and += operators (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `+` and `+=` operators are supported by the built-in [integral](#) and [floating-point](#) numeric types, the [string](#) type, and [delegate](#) types.

For information about the arithmetic `+` operator, see the [Unary plus and minus operators](#) and [Addition operator](#) + sections of the [Arithmetic operators](#) article.

String concatenation

When one or both operands are of type [string](#), the `+` operator concatenates the string representations of its operands (the string representation of `null` is an empty string):

```
Console.WriteLine("Forgot" + "white space");
Console.WriteLine("Probably the oldest constant: " + Math.PI);
Console.WriteLine(null + "Nothing to add.");
// Output:
// Forgotwhite space
// Probably the oldest constant: 3.14159265358979
// Nothing to add.
```

Beginning with C# 6, [string interpolation](#) provides a more convenient way to format strings:

```
Console.WriteLine($"Probably the oldest constant: {Math.PI:F2}");
// Output:
// Probably the oldest constant: 3.14
```

Beginning with C# 10, you can use string interpolation to initialize a constant string when all the expressions used for placeholders are also constant strings.

Delegate combination

For operands of the same [delegate](#) type, the `+` operator returns a new delegate instance that, when invoked, invokes the left-hand operand and then invokes the right-hand operand. If any of the operands is `null`, the `+` operator returns the value of another operand (which also might be `null`). The following example shows how delegates can be combined with the `+` operator:

```
Action a = () => Console.Write("a");
Action b = () => Console.Write("b");
Action ab = a + b;
ab(); // output: ab
```

To perform delegate removal, use the `-` operator.

For more information about delegate types, see [Delegates](#).

Addition assignment operator +=

An expression using the `+=` operator, such as

```
x += y
```

is equivalent to

```
x = x + y
```

except that `x` is only evaluated once.

The following example demonstrates the usage of the `+=` operator:

```
int i = 5;
i += 9;
Console.WriteLine(i);
// Output: 14

string story = "Start. ";
story += "End.";
Console.WriteLine(story);
// Output: Start. End.

Action printer = () => Console.Write("a");
printer(); // output: a

Console.WriteLine();
printer += () => Console.Write("b");
printer(); // output: ab
```

You also use the `+=` operator to specify an event handler method when you subscribe to an [event](#). For more information, see [How to: subscribe to and unsubscribe from events](#).

Operator overloadability

A user-defined type can [overload](#) the `+` operator. When a binary `+` operator is overloaded, the `+=` operator is also implicitly overloaded. A user-defined type cannot explicitly overload the `+=` operator.

C# language specification

For more information, see the [Unary plus operator](#) and [Addition operator](#) sections of the [C# language specification](#).

See also

- [C# reference](#)
- [C# operators and expressions](#)
- [How to concatenate multiple strings](#)
- [Events](#)
- [Arithmetic operators](#)
- [- and -= operators](#)

- and -= operators (C# reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

The `-` and `-=` operators are supported by the built-in [integral](#) and [floating-point](#) numeric types and [delegate](#) types.

For information about the arithmetic `-` operator, see the [Unary plus and minus operators](#) and [Subtraction operator](#) - sections of the [Arithmetic operators](#) article.

Delegate removal

For operands of the same [delegate](#) type, the `-` operator returns a delegate instance that is calculated as follows:

- If both operands are non-null and the invocation list of the right-hand operand is a proper contiguous sublist of the invocation list of the left-hand operand, the result of the operation is a new invocation list that is obtained by removing the right-hand operand's entries from the invocation list of the left-hand operand. If the right-hand operand's list matches multiple contiguous sublists in the left-hand operand's list, only the right-most matching sublist is removed. If removal results in an empty list, the result is `null`.

```
Action a = () => Console.Write("a");
Action b = () => Console.Write("b");

var abbaab = a + b + b + a + a + b;
abbaab(); // output: abbaab
Console.WriteLine();

var ab = a + b;
var abba = abbaab - ab;
abba(); // output: abba
Console.WriteLine();

var nihil = abbaab - abbaab;
Console.WriteLine(nihil is null); // output: True
```

- If the invocation list of the right-hand operand is not a proper contiguous sublist of the invocation list of the left-hand operand, the result of the operation is the left-hand operand. For example, removing a delegate that is not part of the multicast delegate does nothing and results in the unchanged multicast delegate.

```

Action a = () => Console.Write("a");
Action b = () => Console.Write("b");

var abbaab = a + b + b + a + a + b;
var aba = a + b + a;

var first = abbaab - aba;
first(); // output: abbaab
Console.WriteLine();
Console.WriteLine(object.ReferenceEquals(abbaab, first)); // output: True

Action a2 = () => Console.Write("a");
var changed = aba - a;
changed(); // output: ab
Console.WriteLine();
var unchanged = aba - a2;
unchanged(); // output: aba
Console.WriteLine();
Console.WriteLine(object.ReferenceEquals(aba, unchanged)); // output: True

```

The preceding example also demonstrates that during delegate removal delegate instances are compared. For example, delegates that are produced from evaluation of identical [lambda expressions](#) are not equal. For more information about delegate equality, see the [Delegate equality operators](#) section of the [C# language specification](#).

- If the left-hand operand is `null`, the result of the operation is `null`. If the right-hand operand is `null`, the result of the operation is the left-hand operand.

```

Action a = () => Console.Write("a");

var nothing = null - a;
Console.WriteLine(nothing is null); // output: True

var first = a - null;
a(); // output: a
Console.WriteLine();
Console.WriteLine(object.ReferenceEquals(first, a)); // output: True

```

To combine delegates, use the [+ operator](#).

For more information about delegate types, see [Delegates](#).

Subtraction assignment operator -=

An expression using the `-=` operator, such as

```
x -= y
```

is equivalent to

```
x = x - y
```

except that `x` is only evaluated once.

The following example demonstrates the usage of the `-=` operator:

```
int i = 5;
i -= 9;
Console.WriteLine(i);
// Output: -4

Action a = () => Console.Write("a");
Action b = () => Console.Write("b");
var printer = a + b + a;
printer(); // output: aba

Console.WriteLine();
printer -= a;
printer(); // output: ab
```

You also use the `-=` operator to specify an event handler method to remove when you unsubscribe from an [event](#). For more information, see [How to subscribe to and unsubscribe from events](#).

Operator overloadability

A user-defined type can [overload](#) the `-` operator. When a binary `-` operator is overloaded, the `-=` operator is also implicitly overloaded. A user-defined type cannot explicitly overload the `-=` operator.

C# language specification

For more information, see the [Unary minus operator](#) and [Subtraction operator](#) sections of the [C# language specification](#).

?: operator (C# reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

The conditional operator `?:`, also known as the ternary conditional operator, evaluates a Boolean expression and returns the result of one of the two expressions, depending on whether the Boolean expression evaluates to `true` or `false`, as the following example shows:

```
string GetWeatherDisplay(double tempInCelsius) => tempInCelsius < 20.0 ? "Cold." : "Perfect!";

Console.WriteLine(GetWeatherDisplay(15)); // output: Cold.
Console.WriteLine(GetWeatherDisplay(27)); // output: Perfect!
```

As the preceding example shows, the syntax for the conditional operator is as follows:

```
condition ? consequent : alternative
```

The `condition` expression must evaluate to `true` or `false`. If `condition` evaluates to `true`, the `consequent` expression is evaluated, and its result becomes the result of the operation. If `condition` evaluates to `false`, the `alternative` expression is evaluated, and its result becomes the result of the operation. Only `consequent` or `alternative` is evaluated.

Beginning with C# 9.0, conditional expressions are target-typed. That is, if a target type of a conditional expression is known, the types of `consequent` and `alternative` must be implicitly convertible to the target type, as the following example shows:

```
var rand = new Random();
var condition = rand.NextDouble() > 0.5;

int? x = condition ? 12 : null;

IEnumerable<int> xs = x is null ? new List<int>() { 0, 1 } : new int[] { 2, 3 };
```

If a target type of a conditional expression is unknown (for example, when you use the `var` keyword) or in C# 8.0 and earlier, the type of `consequent` and `alternative` must be the same or there must be an implicit conversion from one type to the other:

```
var rand = new Random();
var condition = rand.NextDouble() > 0.5;

var x = condition ? 12 : (int?)null;
```

The conditional operator is right-associative, that is, an expression of the form

```
a ? b : c ? d : e
```

is evaluated as

```
a ? b : (c ? d : e)
```

TIP

You can use the following mnemonic device to remember how the conditional operator is evaluated:

```
is this condition true ? yes : no
```

Conditional ref expression

Beginning with C# 7.2, a [ref local](#) or [ref readonly local](#) variable can be assigned conditionally with a conditional ref expression. You can also use a conditional ref expression as a [reference return value](#) or as a [ref method argument](#).

The syntax for a conditional ref expression is as follows:

```
condition ? ref consequent : ref alternative
```

Like the original conditional operator, a conditional ref expression evaluates only one of the two expressions: either `consequent` or `alternative`.

In the case of a conditional ref expression, the type of `consequent` and `alternative` must be the same. Conditional ref expressions are not target-typed.

The following example demonstrates the usage of a conditional ref expression:

```
var smallArray = new int[] { 1, 2, 3, 4, 5 };
var largeArray = new int[] { 10, 20, 30, 40, 50 };

int index = 7;
ref int refValue = ref ((index < 5) ? ref smallArray[index] : ref largeArray[index - 5]);
refValue = 0;

index = 2;
((index < 5) ? ref smallArray[index] : ref largeArray[index - 5]) = 100;

Console.WriteLine(string.Join(" ", smallArray));
Console.WriteLine(string.Join(" ", largeArray));
// Output:
// 1 2 100 4 5
// 10 20 0 40 50
```

Conditional operator and an `if` statement

Use of the conditional operator instead of an `if` statement might result in more concise code in cases when you need conditionally to compute a value. The following example demonstrates two ways to classify an integer as negative or nonnegative:

```
int input = new Random().Next(-5, 5);

string classify;
if (input >= 0)
{
    classify = "nonnegative";
}
else
{
    classify = "negative";
}

classify = (input >= 0) ? "nonnegative" : "negative";
```

Operator overloadability

A user-defined type cannot overload the conditional operator.

C# language specification

For more information, see the [Conditional operator](#) section of the [C# language specification](#).

! (null-forgiving) operator (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Available in C# 8.0 and later, the unary postfix `!` operator is the null-forgiving, or null-suppression, operator. In an enabled [nullable annotation context](#), you use the null-forgiving operator to declare that expression `x` of a reference type isn't `null`: `x!`. The unary prefix `!` operator is the [logical negation operator](#).

The null-forgiving operator has no effect at run time. It only affects the compiler's static flow analysis by changing the null state of the expression. At run time, expression `x!` evaluates to the result of the underlying expression `x`.

For more information about the nullable reference types feature, see [Nullable reference types](#).

Examples

One of the use cases of the null-forgiving operator is in testing the argument validation logic. For example, consider the following class:

```
#nullable enable
public class Person
{
    public Person(string name) => Name = name ?? throw new ArgumentNullException(nameof(name));

    public string Name { get; }
}
```

Using the [MSTest test framework](#), you can create the following test for the validation logic in the constructor:

```
[TestMethod, ExpectedException(typeof(ArgumentNullException))]
public void NullNameShouldThrowTest()
{
    var person = new Person(null!);
}
```

Without the null-forgiving operator, the compiler generates the following warning for the preceding code:

Warning CS8625: Cannot convert null literal to non-nullable reference type. By using the null-forgiving operator, you inform the compiler that passing `null` is expected and shouldn't be warned about.

You can also use the null-forgiving operator when you definitely know that an expression cannot be `null` but the compiler doesn't manage to recognize that. In the following example, if the `IsValid` method returns `true`, its argument is not `null` and you can safely dereference it:

```
public static void Main()
{
    Person? p = Find("John");
    if (IsValid(p))
    {
        Console.WriteLine($"Found {p!.Name}");
    }
}

public static bool IsValid(Person? person)
    => person is not null && person.Name is not null;
```

Without the null-forgiving operator, the compiler generates the following warning for the `p.Name` code:

```
Warning CS8602: Dereference of a possibly null reference .
```

If you can modify the `IsValid` method, you can use the [NotNullWhen](#) attribute to inform the compiler that an argument of the `IsValid` method cannot be `null` when the method returns `true`:

```
public static void Main()
{
    Person? p = Find("John");
    if (IsValid(p))
    {
        Console.WriteLine($"Found {p.Name}");
    }
}

public static bool IsValid([NotNullWhen(true)] Person? person)
    => person is not null && person.Name is not null;
```

In the preceding example, you don't need to use the null-forgiving operator because the compiler has enough information to find out that `p` cannot be `null` inside the `if` statement. For more information about the attributes that allow you to provide additional information about the null state of a variable, see [Upgrade APIs with attributes to define null expectations](#).

C# language specification

For more information, see [The null-forgiving operator](#) section of the [draft of the nullable reference types specification](#).

- [Tutorial: Design with nullable reference types](#)

?? and ??= operators (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The null-coalescing operator `??` returns the value of its left-hand operand if it isn't `null`; otherwise, it evaluates the right-hand operand and returns its result. The `??` operator doesn't evaluate its right-hand operand if the left-hand operand evaluates to non-null.

Available in C# 8.0 and later, the null-coalescing assignment operator `??=` assigns the value of its right-hand operand to its left-hand operand only if the left-hand operand evaluates to `null`. The `??=` operator doesn't evaluate its right-hand operand if the left-hand operand evaluates to non-null.

```
List<int> numbers = null;
int? a = null;

(numbers ??= new List<int>()).Add(5);
Console.WriteLine(string.Join(" ", numbers)); // output: 5

numbers.Add(a ??= 0);
Console.WriteLine(string.Join(" ", numbers)); // output: 5 0
Console.WriteLine(a); // output: 0
```

The left-hand operand of the `??=` operator must be a variable, a [property](#), or an [indexer](#) element.

In C# 7.3 and earlier, the type of the left-hand operand of the `??` operator must be either a [reference type](#) or a [nullable value type](#). Beginning with C# 8.0, that requirement is replaced with the following: the type of the left-hand operand of the `??` and `??=` operators cannot be a non-nullable value type. In particular, beginning with C# 8.0, you can use the null-coalescing operators with unconstrained type parameters:

```
private static void Display<T>(T a, T backup)
{
    Console.WriteLine(a ?? backup);
}
```

The null-coalescing operators are right-associative. That is, expressions of the form

```
a ?? b ?? c
d ??= e ??= f
```

are evaluated as

```
a ?? (b ?? c)
d ??= (e ??= f)
```

Examples

The `??` and `??=` operators can be useful in the following scenarios:

- In expressions with the [null-conditional operators](#) `?.` and `?[]`, you can use the `??` operator to provide an alternative expression to evaluate in case the result of the expression with null-conditional operations is `null`:

```
double SumNumbers(List<double[]> setsOfNumbers, int indexOfSetToSum)
{
    return setsOfNumbers?[indexOfSetToSum]?.Sum() ?? double.NaN;
}

var sum = SumNumbers(null, 0);
Console.WriteLine(sum); // output: NaN
```

- When you work with [nullable value types](#) and need to provide a value of an underlying value type, use the `??` operator to specify the value to provide in case a nullable type value is `null`:

```
int? a = null;
int b = a ?? -1;
Console.WriteLine(b); // output: -1
```

Use the [Nullable<T>.GetValueOrDefault\(\)](#) method if the value to be used when a nullable type value is `null` should be the default value of the underlying value type.

- Beginning with C# 7.0, you can use a [throw expression](#) as the right-hand operand of the `??` operator to make the argument-checking code more concise:

```
public string Name
{
    get => name;
    set => name = value ?? throw new ArgumentNullException(nameof(value), "Name cannot be null");
}
```

The preceding example also demonstrates how to use [expression-bodied members](#) to define a property.

- Beginning with C# 8.0, you can use the `??=` operator to replace the code of the form

```
if (variable is null)
{
    variable = expression;
}
```

with the following code:

```
variable ??= expression;
```

Operator overloadability

The operators `??` and `??=` cannot be overloaded.

C# language specification

For more information about the `??` operator, see [The null coalescing operator](#) section of the [C# language specification](#).

For more information about the `??=` operator, see the [feature proposal note](#).

- [C# reference](#)

- C# operators and expressions
- ?. and ?[] operators
- ?:: operator

=> operator (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `=>` token is supported in two forms: as the [lambda operator](#) and as a separator of a member name and the member implementation in an [expression body definition](#).

Lambda operator

In [lambda expressions](#), the lambda operator `=>` separates the input parameters on the left side from the lambda body on the right side.

The following example uses the [LINQ](#) feature with method syntax to demonstrate the usage of lambda expressions:

```
string[] words = { "bot", "apple", "apricot" };
int minLength = words
    .Where(w => w.StartsWith("a"))
    .Min(w => w.Length);
Console.WriteLine(minLength);    // output: 5

int[] numbers = { 4, 7, 10 };
int product = numbers.Aggregate(1, (interim, next) => interim * next);
Console.WriteLine(product);    // output: 280
```

Input parameters of a lambda expression are strongly typed at compile time. When the compiler can infer the types of input parameters, like in the preceding example, you may omit type declarations. If you need to specify the type of input parameters, you must do that for each parameter, as the following example shows:

```
int[] numbers = { 4, 7, 10 };
int product = numbers.Aggregate(1, (int interim, int next) => interim * next);
Console.WriteLine(product);    // output: 280
```

The following example shows how to define a lambda expression without input parameters:

```
Func<string> greet = () => "Hello, World!";
Console.WriteLine(greet());
```

For more information, see [Lambda expressions](#).

Expression body definition

An expression body definition has the following general syntax:

```
member => expression;
```

where `expression` is a valid expression. The return type of `expression` must be implicitly convertible to the member's return type. If the member:

- Has a `void` return type or
- Is a:

- Constructor
- Finalizer
- Property or indexer `set` accessor

`expression` must be a [statement expression](#). Because the expression's result is discarded, the return type of that expression can be any type.

The following example shows an expression body definition for a `Person.ToString` method:

```
public override string ToString() => $"{fname} {lname}".Trim();
```

It's a shorthand version of the following method definition:

```
public override string ToString()
{
    return $"{fname} {lname}".Trim();
}
```

Expression body definitions for methods, operators, and read-only properties are supported beginning with C# 6. Expression body definitions for constructors, finalizers, and property and indexer accessors are supported beginning with C# 7.0.

For more information, see [Expression-bodied members](#).

Operator overloadability

The `=>` operator cannot be overloaded.

C# language specification

For more information about the lambda operator, see the [Anonymous function expressions](#) section of the [C# language specification](#).

See also

- [C# reference](#)
- [C# operators and expressions](#)

:: operator (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

Use the namespace alias qualifier `::` to access a member of an aliased namespace. You can use the `::` qualifier only between two identifiers. The left-hand identifier can be any of the following aliases:

- A namespace alias created with a [using alias directive](#):

```
using forwinforms = System.Drawing;
using forwpf = System.Windows;

public class Converters
{
    public static forwpf::Point Convert(forwinforms::Point point) => new forwpf::Point(point.X,
point.Y);
}
```

- An [extern alias](#).
- The `global` alias, which is the global namespace alias. The global namespace is the namespace that contains namespaces and types that are not declared inside a named namespace. When used with the `::` qualifier, the `global` alias always references the global namespace, even if there is the user-defined `global` namespace alias.

The following example uses the `global` alias to access the .NET [System](#) namespace, which is a member of the global namespace. Without the `global` alias, the user-defined `System` namespace, which is a member of the `MyCompany.MyProduct` namespace, would be accessed:

```
namespace MyCompany.MyProduct.System
{
    class Program
    {
        static void Main() => global::System.Console.WriteLine("Using global alias");
    }

    class Console
    {
        string Suggestion => "Consider renaming this class";
    }
}
```

NOTE

The `global` keyword is the global namespace alias only when it's the left-hand identifier of the `::` qualifier.

You can also use the `.` [token](#) to access a member of an aliased namespace. However, the `.` token is also used to access a type member. The `::` qualifier ensures that its left-hand identifier always references a namespace alias, even if there exists a type or namespace with the same name.

C# language specification

For more information, see the [Namespace alias qualifiers](#) section of the [C# language specification](#).

See also

- [C# reference](#)
- [C# operators and expressions](#)

await operator (C# reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

The `await` operator suspends evaluation of the enclosing `async` method until the asynchronous operation represented by its operand completes. When the asynchronous operation completes, the `await` operator returns the result of the operation, if any. When the `await` operator is applied to the operand that represents an already completed operation, it returns the result of the operation immediately without suspension of the enclosing method. The `await` operator doesn't block the thread that evaluates the `async` method. When the `await` operator suspends the enclosing `async` method, the control returns to the caller of the method.

In the following example, the `HttpClient.GetByteArrayAsync` method returns the `Task<byte[]>` instance, which represents an asynchronous operation that produces a byte array when it completes. Until the operation completes, the `await` operator suspends the `DownloadDocsMainPageAsync` method. When `DownloadDocsMainPageAsync` gets suspended, control is returned to the `Main` method, which is the caller of `DownloadDocsMainPageAsync`. The `Main` method executes until it needs the result of the asynchronous operation performed by the `DownloadDocsMainPageAsync` method. When `GetByteArrayAsync` gets all the bytes, the rest of the `DownloadDocsMainPageAsync` method is evaluated. After that, the rest of the `Main` method is evaluated.

```
using System;
using System.Net.Http;
using System.Threading.Tasks;

public class AwaitOperator
{
    public static async Task Main()
    {
        Task<int> downloading = DownloadDocsMainPageAsync();
        Console.WriteLine($"{nameof(Main)}: Launched downloading.");

        int bytesLoaded = await downloading;
        Console.WriteLine($"{nameof(Main)}: Downloaded {bytesLoaded} bytes.");
    }

    private static async Task<int> DownloadDocsMainPageAsync()
    {
        Console.WriteLine($"{nameof(DownloadDocsMainPageAsync)}: About to start downloading.");

        var client = new HttpClient();
        byte[] content = await client.GetByteArrayAsync("https://docs.microsoft.com/en-us/");

        Console.WriteLine($"{nameof(DownloadDocsMainPageAsync)}: Finished downloading.");
        return content.Length;
    }
}

// Output similar to:
// DownloadDocsMainPageAsync: About to start downloading.
// Main: Launched downloading.
// DownloadDocsMainPageAsync: Finished downloading.
// Main: Downloaded 27700 bytes.
```

The preceding example uses the `async Main` method, which is possible beginning with C# 7.1. For more information, see the [await operator in the Main method](#) section.

NOTE

For an introduction to asynchronous programming, see [Asynchronous programming with async and await](#). Asynchronous programming with `async` and `await` follows the [task-based asynchronous pattern](#).

You can use the `await` operator only in a method, [lambda expression](#), or [anonymous method](#) that is modified by the `async` keyword. Within an `async` method, you can't use the `await` operator in the body of a synchronous function, inside the block of a [lock statement](#), and in an `unsafe` context.

The operand of the `await` operator is usually of one of the following .NET types: [Task](#), [Task<TResult>](#), [ValueTask](#), or [ValueTask<TResult>](#). However, any awaitable expression can be the operand of the `await` operator. For more information, see the [Awaitable expressions](#) section of the [C# language specification](#).

The type of expression `await t` is `TResult` if the type of expression `t` is [Task<TResult>](#) or [ValueTask<TResult>](#). If the type of `t` is [Task](#) or [ValueTask](#), the type of `await t` is `void`. In both cases, if `t` throws an exception, `await t` rethrows the exception. For more information about exception handling, see the [Exceptions in async methods](#) section of the [try-catch statement](#) article.

The `async` and `await` keywords are available in C# 5 and later.

Asynchronous streams and disposables

Beginning with C# 8.0, you can work with asynchronous streams and disposables.

You use the `await foreach` statement to consume an asynchronous stream of data. For more information, see the [foreach statement](#) section of the [Iteration statements](#) article and the [Asynchronous streams](#) section of the [What's new in C# 8.0](#) article.

You use the `await using` statement to work with an asynchronously disposable object, that is, an object of a type that implements an [IAsyncDisposable](#) interface. For more information, see the [Using async disposable](#) section of the [Implement a DisposeAsync method](#) article.

await operator in the Main method

Beginning with C# 7.1, the [Main method](#), which is the application entry point, can return `Task` or `Task<int>`, enabling it to be `async` so you can use the `await` operator in its body. In earlier C# versions, to ensure that the `Main` method waits for the completion of an asynchronous operation, you can retrieve the value of the [Task<TResult>.Result](#) property of the [Task<TResult>](#) instance that is returned by the corresponding `async` method. For asynchronous operations that don't produce a value, you can call the [Task.Wait](#) method. For information about how to select the language version, see [C# language versioning](#).

C# language specification

For more information, see the [Await expressions](#) section of the [C# language specification](#).

default value expressions (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

A default value expression produces the [default value](#) of a type. There are two kinds of default value expressions: the [default operator](#) call and a [default literal](#).

You also use the `default` keyword as the default case label within a [switch statement](#).

default operator

The argument to the `default` operator must be the name of a type or a type parameter, as the following example shows:

```
Console.WriteLine(default(int)); // output: 0
Console.WriteLine(default(object) is null); // output: True

void DisplayDefaultOf<T>()
{
    var val = default(T);
    Console.WriteLine($"Default value of {typeof(T)} is {(val == null ? "null" : val.ToString())}.");
}

DisplayDefaultOf<int?>();
DisplayDefaultOf<System.Numerics.Complex>();
DisplayDefaultOf<System.Collections.Generic.List<int>>>();
// Output:
// Default value of System.Nullable`1[System.Int32] is null.
// Default value of System.Numerics.Complex is (0, 0).
// Default value of System.Collections.Generic.List`1[System.Int32] is null.
```

default literal

Beginning with C# 7.1, you can use the `default` literal to produce the default value of a type when the compiler can infer the expression type. The `default` literal expression produces the same value as the `default(T)` expression where `T` is the inferred type. You can use the `default` literal in any of the following cases:

- In the assignment or initialization of a variable.
- In the declaration of the default value for an [optional method parameter](#).
- In a method call to provide an argument value.
- In a [return statement](#) or as an expression in an [expression-bodied member](#).

The following example shows the usage of the `default` literal:

```

T[] InitializeArray<T>(int length, T initialValue = default)
{
    if (length < 0)
    {
        throw new ArgumentOutOfRangeException(nameof(length), "Array length must be nonnegative.");
    }

    var array = new T[length];
    for (var i = 0; i < length; i++)
    {
        array[i] = initialValue;
    }
    return array;
}

void Display<T>(T[] values) => Console.WriteLine($"[ {string.Join(", ", values)} ]");

Display(InitializeArray<int>(3)); // output: [ 0, 0, 0 ]
Display(InitializeArray<bool>(4, default)); // output: [ False, False, False, False ]

System.Numerics.Complex fillValue = default;
Display(InitializeArray(3, fillValue)); // output: [ (0, 0), (0, 0), (0, 0) ]

```

C# language specification

For more information, see the [Default value expressions](#) section of the [C# language specification](#).

For more information about the `default` literal, see the [feature proposal note](#).

See also

- [C# reference](#)
- [C# operators and expressions](#)
- [Default values of C# types](#)
- [Generics in .NET](#)

delegate operator (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `delegate` operator creates an anonymous method that can be converted to a delegate type:

```
Func<int, int, int> sum = delegate (int a, int b) { return a + b; };  
Console.WriteLine(sum(3, 4)); // output: 7
```

NOTE

Beginning with C# 3, lambda expressions provide a more concise and expressive way to create an anonymous function. Use the [=> operator](#) to construct a lambda expression:

```
Func<int, int, int> sum = (a, b) => a + b;  
Console.WriteLine(sum(3, 4)); // output: 7
```

For more information about features of lambda expressions, for example, capturing outer variables, see [Lambda expressions](#).

When you use the `delegate` operator, you might omit the parameter list. If you do that, the created anonymous method can be converted to a delegate type with any list of parameters, as the following example shows:

```
Action greet = delegate { Console.WriteLine("Hello!"); };  
greet();  
  
Action<int, double> introduce = delegate { Console.WriteLine("This is world!"); };  
introduce(42, 2.7);  
  
// Output:  
// Hello!  
// This is world!
```

That's the only functionality of anonymous methods that is not supported by lambda expressions. In all other cases, a lambda expression is a preferred way to write inline code.

Beginning with C# 9.0, you can use [discards](#) to specify two or more input parameters of an anonymous method that aren't used by the method:

```
Func<int, int, int> constant = delegate (int _, int _) { return 42; };  
Console.WriteLine(constant(3, 4)); // output: 42
```

For backwards compatibility, if only a single parameter is named `_`, `_` is treated as the name of that parameter within an anonymous method.

Also beginning with C# 9.0, you can use the `static` modifier at the declaration of an anonymous method:

```
Func<int, int, int> sum = static delegate (int a, int b) { return a + b; };  
Console.WriteLine(sum(10, 4)); // output: 14
```

A static anonymous method can't capture local variables or instance state from enclosing scopes.

You also use the `delegate` keyword to declare a [delegate type](#).

C# language specification

For more information, see the [Anonymous function expressions](#) section of the [C# language specification](#).

- [=> operator](#)

is operator (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `is` operator checks if the result of an expression is compatible with a given type. For information about the type-testing `is` operator, see the [is operator](#) section of the [Type-testing and cast operators](#) article.

Beginning with C# 7.0, you can also use the `is` operator to match an expression against a pattern, as the following example shows:

```
static bool IsFirstFridayOfOctober(DateTime date) =>
    date is { Month: 10, Day: <=7, DayOfWeek: DayOfWeek.Friday };
```

In the preceding example, the `is` operator matches an expression against a [property pattern](#) (available in C# 8.0 and later) with nested [constant](#) and [relational](#) (available in C# 9.0 and later) patterns.

The `is` operator can be useful in the following scenarios:

- To check the run-time type of an expression, as the following example shows:

```
int i = 34;
object iBoxed = i;
int? jNullable = 42;
if (iBoxed is int a && jNullable is int b)
{
    Console.WriteLine(a + b); // output 76
}
```

The preceding example shows the use of a [declaration pattern](#).

- To check for `null`, as the following example shows:

```
if (input is null)
{
    return;
}
```

When you match an expression against `null`, the compiler guarantees that no user-overloaded `==` or `!=` operator is invoked.

- Beginning with C# 9.0, you can use a [negation pattern](#) to do a non-null check, as the following example shows:

```
if (result is not null)
{
    Console.WriteLine(result.ToString());
}
```

NOTE

For the complete list of patterns supported by the `is` operator, see [Patterns](#).

C# language specification

For more information, see [The is operator](#) section of the [C# language specification](#) and the following C# language proposals:

- [Pattern matching](#)
- [Pattern matching with generics](#)

See also

- [C# reference](#)
- [C# operators and expressions](#)

- [Type-testing and cast operators](#)

nameof expression (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

A `nameof` expression produces the name of a variable, type, or member as the string constant:

```
Console.WriteLine(nameof(System.Collections.Generic)); // output: Generic
Console.WriteLine(nameof(List<int>)); // output: List
Console.WriteLine(nameof(List<int>.Count)); // output: Count
Console.WriteLine(nameof(List<int>.Add)); // output: Add

var numbers = new List<int> { 1, 2, 3 };
Console.WriteLine(nameof(numbers)); // output: numbers
Console.WriteLine(nameof(numbers.Count)); // output: Count
Console.WriteLine(nameof(numbers.Add)); // output: Add
```

As the preceding example shows, in the case of a type and a namespace, the produced name is not [fully qualified](#).

In the case of [verbatim identifiers](#), the `@` character is not the part of a name, as the following example shows:

```
var @new = 5;
Console.WriteLine(nameof(@new)); // output: new
```

A `nameof` expression is evaluated at compile time and has no effect at run time.

You can use a `nameof` expression to make the argument-checking code more maintainable:

```
public string Name
{
    get => name;
    set => name = value ?? throw new ArgumentNullException(nameof(value), $"{nameof(Name)} cannot be null");
}
```

A `nameof` expression is available in C# 6 and later.

C# language specification

For more information, see the [Nameof expressions](#) section of the [C# language specification](#).

See also

- [C# reference](#)
- [C# operators and expressions](#)
- [CallerArgumentExpression](#)

new operator (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `new` operator creates a new instance of a type.

You can also use the `new` keyword as a [member declaration modifier](#) or a [generic type constraint](#).

Constructor invocation

To create a new instance of a type, you typically invoke one of the [constructors](#) of that type using the `new` operator:

```
var dict = new Dictionary<string, int>();
dict["first"] = 10;
dict["second"] = 20;
dict["third"] = 30;

Console.WriteLine(string.Join("; ", dict.Select(entry => $"{entry.Key}: {entry.Value}")));
// Output:
// first: 10; second: 20; third: 30
```

You can use an [object or collection initializer](#) with the `new` operator to instantiate and initialize an object in one statement, as the following example shows:

```
var dict = new Dictionary<string, int>
{
    ["first"] = 10,
    ["second"] = 20,
    ["third"] = 30
};

Console.WriteLine(string.Join("; ", dict.Select(entry => $"{entry.Key}: {entry.Value}")));
// Output:
// first: 10; second: 20; third: 30
```

Beginning with C# 9.0, constructor invocation expressions are target-typed. That is, if a target type of an expression is known, you can omit a type name, as the following example shows:

```
List<int> xs = new();
List<int> ys = new(capacity: 10_000);
List<int> zs = new() { Capacity = 20_000 };

Dictionary<int, List<int>> lookup = new()
{
    [1] = new() { 1, 2, 3 },
    [2] = new() { 5, 8, 3 },
    [5] = new() { 1, 0, 4 }
};
```

As the preceding example shows, you always use parentheses in a target-typed `new` expression.

If a target type of a `new` expression is unknown (for example, when you use the `var` keyword), you must specify a type name.

Array creation

You also use the `new` operator to create an array instance, as the following example shows:

```
var numbers = new int[3];
numbers[0] = 10;
numbers[1] = 20;
numbers[2] = 30;

Console.WriteLine(string.Join(", ", numbers));
// Output:
// 10, 20, 30
```

Use array initialization syntax to create an array instance and populate it with elements in one statement. The following example shows various ways how you can do that:

```
var a = new int[3] { 10, 20, 30 };
var b = new int[] { 10, 20, 30 };
var c = new[] { 10, 20, 30 };
Console.WriteLine(c.GetType()); // output: System.Int32[]
```

For more information about arrays, see [Arrays](#).

Instantiation of anonymous types

To create an instance of an [anonymous type](#), use the `new` operator and object initializer syntax:

```
var example = new { Greeting = "Hello", Name = "World" };
Console.WriteLine($"{example.Greeting}, {example.Name}!");
// Output:
// Hello, World!
```

Destruction of type instances

You don't have to destroy earlier created type instances. Instances of both reference and value types are destroyed automatically. Instances of value types are destroyed as soon as the context that contains them is destroyed. Instances of reference types are destroyed by the [garbage collector](#) at some unspecified time after the last reference to them is removed.

For type instances that contain unmanaged resources, for example, a file handle, it's recommended to employ deterministic clean-up to ensure that the resources they contain are released as soon as possible. For more information, see the [System.IDisposable](#) API reference and the [using statement](#) article.

Operator overloadability

A user-defined type cannot overload the `new` operator.

C# language specification

For more information, see [The new operator](#) section of the [C# language specification](#).

For more information about a target-typed `new` expression, see the [feature proposal note](#).

sizeof operator (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `sizeof` operator returns the number of bytes occupied by a variable of a given type. The argument to the `sizeof` operator must be the name of an [unmanaged type](#) or a type parameter that is [constrained](#) to be an unmanaged type.

The `sizeof` operator requires an [unsafe](#) context. However, the expressions presented in the following table are evaluated in compile time to the corresponding constant values and don't require an unsafe context:

EXPRESSION	CONSTANT VALUE
<code>sizeof(sbyte)</code>	1
<code>sizeof(byte)</code>	1
<code>sizeof(short)</code>	2
<code>sizeof(ushort)</code>	2
<code>sizeof(int)</code>	4
<code>sizeof(uint)</code>	4
<code>sizeof(long)</code>	8
<code>sizeof(ulong)</code>	8
<code>sizeof(char)</code>	2
<code>sizeof(float)</code>	4
<code>sizeof(double)</code>	8
<code>sizeof(decimal)</code>	16
<code>sizeof(bool)</code>	1

You also don't need to use an unsafe context when the operand of the `sizeof` operator is the name of an [enum](#) type.

The following example demonstrates the usage of the `sizeof` operator:

```

using System;

public struct Point
{
    public Point(byte tag, double x, double y) => (Tag, X, Y) = (tag, x, y);

    public byte Tag { get; }
    public double X { get; }
    public double Y { get; }
}

public class SizeOfOperator
{
    public static void Main()
    {
        Console.WriteLine(sizeof(byte)); // output: 1
        Console.WriteLine(sizeof(double)); // output: 8

        DisplaySizeOf<Point>(); // output: Size of Point is 24
        DisplaySizeOf<decimal>(); // output: Size of System.Decimal is 16

        unsafe
        {
            Console.WriteLine(sizeof(Point*)); // output: 8
        }

        static unsafe void DisplaySizeOf<T>() where T : unmanaged
        {
            Console.WriteLine($"Size of {typeof(T)} is {sizeof(T)}");
        }
    }
}

```

The `sizeof` operator returns a number of bytes that would be allocated by the common language runtime in managed memory. For [struct](#) types, that value includes any padding, as the preceding example demonstrates. The result of the `sizeof` operator might differ from the result of the [Marshal.SizeOf](#) method, which returns the size of a type in *unmanaged* memory.

C# language specification

For more information, see [The sizeof operator](#) section of the [C# language specification](#).

stackalloc expression (C# reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

A `stackalloc` expression allocates a block of memory on the stack. A stack allocated memory block created during the method execution is automatically discarded when that method returns. You cannot explicitly free the memory allocated with `stackalloc`. A stack allocated memory block is not subject to [garbage collection](#) and doesn't have to be pinned with a `fixed` statement.

You can assign the result of a `stackalloc` expression to a variable of one of the following types:

- Beginning with C# 7.2, [System.Span<T>](#) or [System.ReadOnlySpan<T>](#), as the following example shows:

```
int length = 3;
Span<int> numbers = stackalloc int[length];
for (var i = 0; i < length; i++)
{
    numbers[i] = i;
}
```

You don't have to use an [unsafe](#) context when you assign a stack allocated memory block to a [Span<T>](#) or [ReadOnlySpan<T>](#) variable.

When you work with those types, you can use a `stackalloc` expression in [conditional](#) or assignment expressions, as the following example shows:

```
int length = 1000;
Span<byte> buffer = length <= 1024 ? stackalloc byte[length] : new byte[length];
```

Beginning with C# 8.0, you can use a `stackalloc` expression inside other expressions whenever a [Span<T>](#) or [ReadOnlySpan<T>](#) variable is allowed, as the following example shows:

```
Span<int> numbers = stackalloc[] { 1, 2, 3, 4, 5, 6 };
var ind = numbers.IndexOfAny(stackalloc[] { 2, 4, 6, 8 });
Console.WriteLine(ind); // output: 1
```

NOTE

We recommend using [Span<T>](#) or [ReadOnlySpan<T>](#) types to work with stack allocated memory whenever possible.

- A [pointer type](#), as the following example shows:

```
unsafe
{
    int length = 3;
    int* numbers = stackalloc int[length];
    for (var i = 0; i < length; i++)
    {
        numbers[i] = i;
    }
}
```

As the preceding example shows, you must use an `unsafe` context when you work with pointer types.

In the case of pointer types, you can use a `stackalloc` expression only in a local variable declaration to initialize the variable.

The amount of memory available on the stack is limited. If you allocate too much memory on the stack, a [StackOverflowException](#) is thrown. To avoid that, follow the rules below:

- Limit the amount of memory you allocate with `stackalloc`. For example, if the intended buffer size is below a certain limit, you allocate the memory on the stack; otherwise, use an array of the required length, as the following code shows:

```
const int MaxStackLimit = 1024;
Span<byte> buffer = inputLength <= MaxStackLimit ? stackalloc byte[inputLength] : new
byte[inputLength];
```

NOTE

Because the amount of memory available on the stack depends on the environment in which the code is executed, be conservative when you define the actual limit value.

- Avoid using `stackalloc` inside loops. Allocate the memory block outside a loop and reuse it inside the loop.

The content of the newly allocated memory is undefined. You should initialize it before the use. For example, you can use the [Span<T>.Clear](#) method that sets all the items to the default value of type `T`.

Beginning with C# 7.3, you can use array initializer syntax to define the content of the newly allocated memory. The following example demonstrates various ways to do that:

```
Span<int> first = stackalloc int[3] { 1, 2, 3 };
Span<int> second = stackalloc int[] { 1, 2, 3 };
ReadOnlySpan<int> third = stackalloc[] { 1, 2, 3 };
```

In expression `stackalloc T[E]`, `T` must be an [unmanaged type](#) and `E` must evaluate to a non-negative `int` value.

Security

The use of `stackalloc` automatically enables buffer overrun detection features in the common language runtime (CLR). If a buffer overrun is detected, the process is terminated as quickly as possible to minimize the chance that malicious code is executed.

C# language specification

For more information, see the [Stack allocation](#) section of the [C# language specification](#) and the [Permit `stackalloc` in nested contexts](#) feature proposal note.

See also

- [C# reference](#)

- [Memory and span-related types](#)
- [Dos and Don'ts of stackalloc](#)

switch expression (C# reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

Beginning with C# 8.0, you use the `switch` expression to evaluate a single expression from a list of candidate expressions based on a pattern match with an input expression. For information about the `switch` statement that supports `switch`-like semantics in a statement context, see the [switch statement](#) section of the [Selection statements](#) article.

The following example demonstrates a `switch` expression, which converts values of an `enum` representing visual directions in an online map to the corresponding cardinal directions:

```
public static class SwitchExample
{
    public enum Direction
    {
        Up,
        Down,
        Right,
        Left
    }

    public enum Orientation
    {
        North,
        South,
        East,
        West
    }

    public static Orientation ToOrientation(Direction direction) => direction switch
    {
        Direction.Up    => Orientation.North,
        Direction.Right => Orientation.East,
        Direction.Down  => Orientation.South,
        Direction.Left  => Orientation.West,
        _ => throw new ArgumentOutOfRangeException(nameof(direction), $"Not expected direction value: {direction}"),
    };

    public static void Main()
    {
        var direction = Direction.Right;
        Console.WriteLine($"Map view direction is {direction}");
        Console.WriteLine($"Cardinal orientation is {ToOrientation(direction)}");
        // Output:
        // Map view direction is Right
        // Cardinal orientation is East
    }
}
```

The preceding example shows the basic elements of a `switch` expression:

- An expression followed by the `switch` keyword. In the preceding example, it's the `direction` method parameter.
- The `switch` *expression arms*, separated by commas. Each `switch` expression arm contains a *pattern*, an optional *case guard*, the `=>` token, and an *expression*.

At the preceding example, a `switch` expression uses the following patterns:

- A [constant pattern](#): to handle the defined values of the `Direction` enumeration.
- A [discard pattern](#): to handle any integer value that doesn't have the corresponding member of the `Direction` enumeration (for example, `(Direction)10`). That makes the `switch` expression [exhaustive](#).

IMPORTANT

For information about the patterns supported by the `switch` expression and more examples, see [Patterns](#).

The result of a `switch` expression is the value of the expression of the first `switch` expression arm whose pattern matches the input expression and whose case guard, if present, evaluates to `true`. The `switch` expression arms are evaluated in text order.

The compiler generates an error when a lower `switch` expression arm can't be chosen because a higher `switch` expression arm matches all its values.

Case guards

A pattern may be not expressive enough to specify the condition for the evaluation of an arm's expression. In such a case, you can use a case guard. That is an additional condition that must be satisfied together with a matched pattern. A case guard must be a Boolean expression. You specify a case guard after the `when` keyword that follows a pattern, as the following example shows:

```
public readonly struct Point
{
    public Point(int x, int y) => (X, Y) = (x, y);

    public int X { get; }
    public int Y { get; }
}

static Point Transform(Point point) => point switch
{
    { X: 0, Y: 0 } => new Point(0, 0),
    { X: var x, Y: var y } when x < y => new Point(x + y, y),
    { X: var x, Y: var y } when x > y => new Point(x - y, y),
    { X: var x, Y: var y } => new Point(2 * x, 2 * y),
};
```

The preceding example uses [property patterns](#) with nested [var patterns](#).

Non-exhaustive switch expressions

If none of a `switch` expression's patterns matches an input value, the runtime throws an exception. In .NET Core 3.0 and later versions, the exception is a [System.Runtime.CompilerServices.SwitchExpressionException](#). In .NET Framework, the exception is an [InvalidOperationException](#). The compiler generates a warning if a `switch` expression doesn't handle all possible input values.

TIP

To guarantee that a `switch` expression handles all possible input values, provide a `switch` expression arm with a [discard pattern](#).

C# language specification

For more information, see the [switch expression](#) section of the [feature proposal note](#).

- [switch statement](#)

true and false operators (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `true` operator returns the `bool` value `true` to indicate that its operand is definitely true. The `false` operator returns the `bool` value `false` to indicate that its operand is definitely false. The `true` and `false` operators are not guaranteed to complement each other. That is, both the `true` and `false` operator might return the `bool` value `false` for the same operand. If a type defines one of the two operators, it must also define another operator.

TIP

Use the `bool?` type, if you need to support the three-valued logic (for example, when you work with databases that support a three-valued Boolean type). C# provides the `&` and `|` operators that support the three-valued logic with the `bool?` operands. For more information, see the [Nullable Boolean logical operators](#) section of the [Boolean logical operators](#) article.

Boolean expressions

A type with the defined `true` operator can be the type of a result of a controlling conditional expression in the `if`, `do`, `while`, and `for` statements and in the [conditional operator](#) `?:`. For more information, see the [Boolean expressions](#) section of the [C# language specification](#).

User-defined conditional logical operators

If a type with the defined `true` and `false` operators [overloads](#) the [logical OR operator](#) `|` or the [logical AND operator](#) `&` in a certain way, the [conditional logical OR operator](#) `||` or [conditional logical AND operator](#) `&&`, respectively, can be evaluated for the operands of that type. For more information, see the [User-defined conditional logical operators](#) section of the [C# language specification](#).

Example

The following example presents the type that defines both `true` and `false` operators. The type also overloads the logical AND operator `&` in such a way that the `&&` operator also can be evaluated for the operands of that type.

```

using System;

public struct LaunchStatus
{
    public static readonly LaunchStatus Green = new LaunchStatus(0);
    public static readonly LaunchStatus Yellow = new LaunchStatus(1);
    public static readonly LaunchStatus Red = new LaunchStatus(2);

    private int status;

    private LaunchStatus(int status)
    {
        this.status = status;
    }

    public static bool operator true(LaunchStatus x) => x == Green || x == Yellow;
    public static bool operator false(LaunchStatus x) => x == Red;

    public static LaunchStatus operator &(LaunchStatus x, LaunchStatus y)
    {
        if (x == Red || y == Red || (x == Yellow && y == Yellow))
        {
            return Red;
        }

        if (x == Yellow || y == Yellow)
        {
            return Yellow;
        }

        return Green;
    }

    public static bool operator ==(LaunchStatus x, LaunchStatus y) => x.status == y.status;
    public static bool operator !=(LaunchStatus x, LaunchStatus y) => !(x == y);

    public override bool Equals(object obj) => obj is LaunchStatus other && this == other;
    public override int GetHashCode() => status;
}

public class LaunchStatusTest
{
    public static void Main()
    {
        LaunchStatus okToLaunch = GetFuelLaunchStatus() && GetNavigationLaunchStatus();
        Console.WriteLine(okToLaunch ? "Ready to go!" : "Wait!");
    }

    static LaunchStatus GetFuelLaunchStatus()
    {
        Console.WriteLine("Getting fuel launch status...");
        return LaunchStatus.Red;
    }

    static LaunchStatus GetNavigationLaunchStatus()
    {
        Console.WriteLine("Getting navigation launch status...");
        return LaunchStatus.Yellow;
    }
}

```

Notice the short-circuiting behavior of the `&&` operator. When the `GetFuelLaunchStatus` method returns `LaunchStatus.Red`, the right-hand operand of the `&&` operator is not evaluated. That is because `LaunchStatus.Red` is definitely false. Then the result of the logical AND doesn't depend on the value of the right-hand operand. The output of the example is as follows:

```
Getting fuel launch status...  
Wait!
```

See also

- [C# reference](#)
- [C# operators and expressions](#)

with expression (C# reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

Available in C# 9.0 and later, a `with` expression produces a copy of its operand with the specified properties and fields modified:

```
using System;

public class WithExpressionBasicExample
{
    public record NamedPoint(string Name, int X, int Y);

    public static void Main()
    {
        var p1 = new NamedPoint("A", 0, 0);
        Console.WriteLine($"{nameof(p1)}: {p1}"); // output: p1: NamedPoint { Name = A, X = 0, Y = 0 }

        var p2 = p1 with { Name = "B", X = 5 };
        Console.WriteLine($"{nameof(p2)}: {p2}"); // output: p2: NamedPoint { Name = B, X = 5, Y = 0 }

        var p3 = p1 with
        {
            Name = "C",
            Y = 4
        };
        Console.WriteLine($"{nameof(p3)}: {p3}"); // output: p3: NamedPoint { Name = C, X = 0, Y = 4 }

        Console.WriteLine($"{nameof(p1)}: {p1}"); // output: p1: NamedPoint { Name = A, X = 0, Y = 0 }

        var apples = new { Item = "Apples", Price = "1.19" };
        Console.WriteLine($"original apples: {apples}");
        var saleApples = apples with { Price = "0.79" };
        Console.WriteLine($"sale apples: {saleApples}");
    }
}
```

As the preceding example shows, you use [object initializer](#) syntax to specify what members to modify and their new values.

In C# 9.0, a left-hand operand of a `with` expression must be of a [record type](#). Beginning with C# 10, a left-hand operand of a `with` expression can also be of a [structure type](#) or an [anonymous type](#).

The result of a `with` expression has the same run-time type as the expression's operand, as the following example shows:

```

using System;

public class InheritanceExample
{
    public record Point(int X, int Y);
    public record NamedPoint(string Name, int X, int Y) : Point(X, Y);

    public static void Main()
    {
        Point p1 = new NamedPoint("A", 0, 0);
        Point p2 = p1 with { X = 5, Y = 3 };
        Console.WriteLine(p2 is NamedPoint); // output: True
        Console.WriteLine(p2); // output: NamedPoint { X = 5, Y = 3, Name = A }
    }
}

```

In the case of a reference-type member, only the reference to a member instance is copied when an operand is copied. Both the copy and original operand have access to the same reference-type instance. The following example demonstrates that behavior:

```

using System;
using System.Collections.Generic;

public class ExampleWithReferenceType
{
    public record TaggedNumber(int Number, List<string> Tags)
    {
        public string PrintTags() => string.Join(", ", Tags);
    }

    public static void Main()
    {
        var original = new TaggedNumber(1, new List<string> { "A", "B" });

        var copy = original with { Number = 2 };
        Console.WriteLine($"Tags of {nameof(copy)}: {copy.PrintTags()}");
        // output: Tags of copy: A, B

        original.Tags.Add("C");
        Console.WriteLine($"Tags of {nameof(copy)}: {copy.PrintTags()}");
        // output: Tags of copy: A, B, C
    }
}

```

Custom copy semantics

Any record class type has the *copy constructor*. That is a constructor with a single parameter of the containing record type. It copies the state of its argument to a new record instance. At evaluation of a `with` expression, the copy constructor gets called to instantiate a new record instance based on an original record. After that, the new instance gets updated according to the specified modifications. By default, the copy constructor is implicit, that is, compiler-generated. If you need to customize the record copy semantics, explicitly declare a copy constructor with the desired behavior. The following example updates the preceding example with an explicit copy constructor. The new copy behavior is to copy list items instead of a list reference when a record is copied:

```

using System;
using System.Collections.Generic;

public class UserDefinedCopyConstructorExample
{
    public record TaggedNumber(int Number, List<string> Tags)
    {
        protected TaggedNumber(TaggedNumber original)
        {
            Number = original.Number;
            Tags = new List<string>(original.Tags);
        }

        public string PrintTags() => string.Join(", ", Tags);
    }

    public static void Main()
    {
        var original = new TaggedNumber(1, new List<string> { "A", "B" });

        var copy = original with { Number = 2 };
        Console.WriteLine($"Tags of {nameof(copy)}: {copy.PrintTags()}");
        // output: Tags of copy: A, B

        original.Tags.Add("C");
        Console.WriteLine($"Tags of {nameof(copy)}: {copy.PrintTags()}");
        // output: Tags of copy: A, B
    }
}

```

You cannot customize the copy semantics for structure types.

C# language specification

For more information, see the following sections of the [records feature proposal note](#):

- [with expression](#)
- [Copy and Clone members](#)

Operator overloading (C# reference)

12/28/2021 • 3 minutes to read • [Edit Online](#)

A user-defined type can overload a predefined C# operator. That is, a type can provide the custom implementation of an operation in case one or both of the operands are of that type. The [Overloadable operators](#) section shows which C# operators can be overloaded.

Use the `operator` keyword to declare an operator. An operator declaration must satisfy the following rules:

- It includes both a `public` and a `static` modifier.
- A unary operator has one input parameter. A binary operator has two input parameters. In each case, at least one parameter must have type `T` or `T?` where `T` is the type that contains the operator declaration.

The following example defines a simplified structure to represent a rational number. The structure overloads some of the [arithmetic operators](#):

```

using System;

public readonly struct Fraction
{
    private readonly int num;
    private readonly int den;

    public Fraction(int numerator, int denominator)
    {
        if (denominator == 0)
        {
            throw new ArgumentException("Denominator cannot be zero.", nameof(denominator));
        }
        num = numerator;
        den = denominator;
    }

    public static Fraction operator +(Fraction a) => a;
    public static Fraction operator -(Fraction a) => new Fraction(-a.num, a.den);

    public static Fraction operator +(Fraction a, Fraction b)
        => new Fraction(a.num * b.den + b.num * a.den, a.den * b.den);

    public static Fraction operator -(Fraction a, Fraction b)
        => a + (-b);

    public static Fraction operator *(Fraction a, Fraction b)
        => new Fraction(a.num * b.num, a.den * b.den);

    public static Fraction operator /(Fraction a, Fraction b)
    {
        if (b.num == 0)
        {
            throw new DivideByZeroException();
        }
        return new Fraction(a.num * b.den, a.den * b.num);
    }

    public override string ToString() => $"{num} / {den}";
}

public static class OperatorOverloading
{
    public static void Main()
    {
        var a = new Fraction(5, 4);
        var b = new Fraction(1, 2);
        Console.WriteLine(-a);    // output: -5 / 4
        Console.WriteLine(a + b); // output: 14 / 8
        Console.WriteLine(a - b); // output: 6 / 8
        Console.WriteLine(a * b); // output: 5 / 8
        Console.WriteLine(a / b); // output: 10 / 4
    }
}

```

You could extend the preceding example by [defining an implicit conversion](#) from `int` to `Fraction`. Then, overloaded operators would support arguments of those two types. That is, it would become possible to add an integer to a fraction and obtain a fraction as a result.

You also use the `operator` keyword to define a custom type conversion. For more information, see [User-defined conversion operators](#).

Overloadable operators

The following table provides information about overloadability of C# operators:

OPERATORS	OVERLOADABILITY
<code>+x</code> , <code>-x</code> , <code>!x</code> , <code>~x</code> , <code>++</code> , <code>--</code> , <code>true</code> , <code>false</code>	These unary operators can be overloaded.
<code>x + y</code> , <code>x - y</code> , <code>x * y</code> , <code>x / y</code> , <code>x % y</code> , <code>x & y</code> , <code>x y</code> , <code>x ^ y</code> , <code>x << y</code> , <code>x >> y</code> , <code>x == y</code> , <code>x != y</code> , <code>x < y</code> , <code>x > y</code> , <code>x <= y</code> , <code>x >= y</code>	These binary operators can be overloaded. Certain operators must be overloaded in pairs; for more information, see the note that follows this table.
<code>x && y</code> , <code>x y</code>	Conditional logical operators cannot be overloaded. However, if a type with the overloaded <code>true</code> and <code>false</code> operators also overloads the <code>&</code> or <code> </code> operator in a certain way, the <code>&&</code> or <code> </code> operator, respectively, can be evaluated for the operands of that type. For more information, see the User-defined conditional logical operators section of the C# language specification .
<code>a[i]</code> , <code>a?[i]</code>	Element access is not considered an overloadable operator, but you can define an indexer .
<code>(T)x</code>	The cast operator cannot be overloaded, but you can define custom type conversions that can be performed by a cast expression. For more information, see User-defined conversion operators .
<code>+=</code> , <code>-=</code> , <code>*=</code> , <code>/=</code> , <code>%=</code> , <code>&=</code> , <code> =</code> , <code>^=</code> , <code><=<</code> , <code>>>=</code>	Compound assignment operators cannot be explicitly overloaded. However, when you overload a binary operator, the corresponding compound assignment operator, if any, is also implicitly overloaded. For example, <code>+=</code> is evaluated using <code>+</code> , which can be overloaded.
<code>^x</code> , <code>x = y</code> , <code>x.y</code> , <code>x?.y</code> , <code>c ? t : f</code> , <code>x ?? y</code> , <code>x ??= y</code> , <code>x.y</code> , <code>x->y</code> , <code>=></code> , <code>f(x)</code> , <code>as</code> , <code>await</code> , <code>checked</code> , <code>unchecked</code> , <code>default</code> , <code>delegate</code> , <code>is</code> , <code>nameof</code> , <code>new</code> , <code>sizeof</code> , <code>stackalloc</code> , <code>switch</code> , <code>typeof</code> , <code>with</code>	These operators cannot be overloaded.

NOTE

The comparison operators must be overloaded in pairs. That is, if either operator of a pair is overloaded, the other operator must be overloaded as well. Such pairs are as follows:

- `==` and `!=` operators
- `<` and `>` operators
- `<=` and `>=` operators

C# language specification

For more information, see the following sections of the [C# language specification](#):

- [Operator overloading](#)
- [Operators](#)

Iteration statements (C# reference)

12/28/2021 • 7 minutes to read • [Edit Online](#)

The following statements repeatedly execute a statement or a block of statements:

- The `for` statement: executes its body while a specified Boolean expression evaluates to `true`.
- The `foreach` statement: enumerates the elements of a collection and executes its body for each element of the collection.
- The `do` statement: conditionally executes its body one or more times.
- The `while` statement: conditionally executes its body zero or more times.

At any point within the body of an iteration statement, you can break out of the loop by using the `break` statement, or step to the next iteration in the loop by using the `continue` statement.

The `for` statement

The `for` statement executes a statement or a block of statements while a specified Boolean expression evaluates to `true`. The following example shows the `for` statement that executes its body while an integer counter is less than three:

```
for (int i = 0; i < 3; i++)
{
    Console.Write(i);
}
// Output:
// 012
```

The preceding example shows the elements of the `for` statement:

- The *initializer* section that is executed only once, before entering the loop. Typically, you declare and initialize a local loop variable in that section. The declared variable can't be accessed from outside the `for` statement.

The *initializer* section in the preceding example declares and initializes an integer counter variable:

```
int i = 0
```

- The *condition* section that determines if the next iteration in the loop should be executed. If it evaluates to `true` or is not present, the next iteration is executed; otherwise, the loop is exited. The *condition* section must be a Boolean expression.

The *condition* section in the preceding example checks if a counter value is less than three:

```
i < 3
```

- The *iterator* section that defines what happens after each execution of the body of the loop.

The *iterator* section in the preceding example increments the counter:

```
i++
```

- The body of the loop, which must be a statement or a block of statements.

The iterator section can contain zero or more of the following statement expressions, separated by commas:

- prefix or postfix [increment](#) expression, such as `++i` or `i++`
- prefix or postfix [decrement](#) expression, such as `--i` or `i--`
- [assignment](#)
- invocation of a method
- [await](#) expression
- creation of an object by using the [new](#) operator

If you don't declare a loop variable in the initializer section, you can use zero or more of the expressions from the preceding list in the initializer section as well. The following example shows several less common usages of the initializer and iterator sections: assigning a value to an external variable in the initializer section, invoking a method in both the initializer and the iterator sections, and changing the values of two variables in the iterator section:

```
int i;
int j = 3;
for (i = 0, Console.WriteLine($"Start: i={i}, j={j}"); i < j; i++, j--, Console.WriteLine($"Step: i={i}, j={j}"))
{
    //...
}
// Output:
// Start: i=0, j=3
// Step: i=1, j=2
// Step: i=2, j=1
```

All the sections of the `for` statement are optional. For example, the following code defines the infinite `for` loop:

```
for ( ; ; )
{
    //...
}
```

The `foreach` statement

The `foreach` statement executes a statement or a block of statements for each element in an instance of the type that implements the [System.Collections.IEnumerable](#) or [System.Collections.Generic.IEnumerable<T>](#) interface, as the following example shows:

```
var fibNumbers = new List<int> { 0, 1, 1, 2, 3, 5, 8, 13 };
foreach (int element in fibNumbers)
{
    Console.Write($"{element} ");
}
// Output:
// 0 1 1 2 3 5 8 13
```

The `foreach` statement isn't limited to those types. You can use it with an instance of any type that satisfies the

following conditions:

- A type has the public parameterless `GetEnumerator` method. Beginning with C# 9.0, the `GetEnumerator` method can be a type's [extension method](#).
- The return type of the `GetEnumerator` method has the public `Current` property and the public parameterless `MoveNext` method whose return type is `bool`.

The following example uses the `foreach` statement with an instance of the `System.Span<T>` type, which doesn't implement any interfaces:

```
Span<int> numbers = new int[] { 3, 14, 15, 92, 6 };
foreach (int number in numbers)
{
    Console.WriteLine($"{number} ");
}
// Output:
// 3 14 15 92 6
```

Beginning with C# 7.3, if the enumerator's `Current` property returns a [reference return value](#) (`ref T` where `T` is the type of a collection element), you can declare an iteration variable with the `ref` or `ref readonly` modifier, as the following example shows:

```
Span<int> storage = stackalloc int[10];
int num = 0;
foreach (ref int item in storage)
{
    item = num++;
}
foreach (ref readonly var item in storage)
{
    Console.WriteLine($"{item} ");
}
// Output:
// 0 1 2 3 4 5 6 7 8 9
```

If the `foreach` statement is applied to `null`, a [NullReferenceException](#) is thrown. If the source collection of the `foreach` statement is empty, the body of the `foreach` statement isn't executed and skipped.

await foreach

Beginning with C# 8.0, you can use the `await foreach` statement to consume an asynchronous stream of data, that is, the collection type that implements the [IAsyncEnumerable<T>](#) interface. Each iteration of the loop may be suspended while the next element is retrieved asynchronously. The following example shows how to use the `await foreach` statement:

```
await foreach (var item in GenerateSequenceAsync())
{
    Console.WriteLine(item);
}
```

You can also use the `await foreach` statement with an instance of any type that satisfies the following conditions:

- A type has the public parameterless `GetAsyncEnumerator` method. That method can be a type's [extension method](#).
- The return type of the `GetAsyncEnumerator` method has the public `Current` property and the public parameterless `MoveNextAsync` method whose return type is `Task<bool>`, `ValueTask<bool>`, or any other

awaitable type whose `awaiter`'s `GetResult` method returns a `bool` value.

By default, stream elements are processed in the captured context. If you want to disable capturing of the context, use the [TaskAsyncEnumerableExtensions.ConfigureAwait](#) extension method. For more information about synchronization contexts and capturing the current context, see [Consuming the Task-based asynchronous pattern](#). For more information about asynchronous streams, see the [Asynchronous streams](#) section of the [What's new in C# 8.0](#) article.

Type of an iteration variable

You can use the `var` keyword to let the compiler infer the type of an iteration variable in the `foreach` statement, as the following code shows:

```
foreach (var item in collection) { }
```

You can also explicitly specify the type of an iteration variable, as the following code shows:

```
IEnumerable<T> collection = new T[5];  
foreach (V item in collection) { }
```

In the preceding form, type `T` of a collection element must be implicitly or explicitly convertible to type `V` of an iteration variable. If an explicit conversion from `T` to `V` fails at run time, the `foreach` statement throws an [InvalidCastException](#). For example, if `T` is a non-sealed class type, `V` can be any interface type, even the one that `T` doesn't implement. At run time, the type of a collection element may be the one that derives from `T` and actually implements `V`. If that's not the case, an [InvalidCastException](#) is thrown.

The `do` statement

The `do` statement executes a statement or a block of statements while a specified Boolean expression evaluates to `true`. Because that expression is evaluated after each execution of the loop, a `do` loop executes one or more times. This differs from a [while](#) loop, which executes zero or more times.

The following example shows the usage of the `do` statement:

```
int n = 0;  
do  
{  
    Console.Write(n);  
    n++;  
} while (n < 5);  
// Output:  
// 01234
```

The `while` statement

The `while` statement executes a statement or a block of statements while a specified Boolean expression evaluates to `true`. Because that expression is evaluated before each execution of the loop, a `while` loop executes zero or more times. This differs from a [do](#) loop, which executes one or more times.

The following example shows the usage of the `while` statement:

```
int n = 0;
while (n < 5)
{
    Console.Write(n);
    n++;
}
// Output:
// 01234
```

C# language specification

Selection statements (C# reference)

12/28/2021 • 5 minutes to read • [Edit Online](#)

The following statements select statements to execute from a number of possible statements based on the value of an expression:

- The `if statement`: selects a statement to execute based on the value of a Boolean expression.
- The `switch statement`: selects a statement list to execute based on a pattern match with an expression.

The `if` statement

An `if` statement can be any of the following two forms:

- An `if` statement with an `else` part selects one of the two statements to execute based on the value of a Boolean expression, as the following example shows:

```
DisplayWeatherReport(15.0); // Output: Cold.
DisplayWeatherReport(24.0); // Output: Perfect!

void DisplayWeatherReport(double tempInCelsius)
{
    if (tempInCelsius < 20.0)
    {
        Console.WriteLine("Cold.");
    }
    else
    {
        Console.WriteLine("Perfect!");
    }
}
```

- An `if` statement without an `else` part executes its body only if a Boolean expression evaluates to `true`, as the following example shows:

```
DisplayMeasurement(45); // Output: The measurement value is 45
DisplayMeasurement(-3); // Output: Warning: not acceptable value! The measurement value is -3

void DisplayMeasurement(double value)
{
    if (value < 0 || value > 100)
    {
        Console.Write("Warning: not acceptable value! ");
    }

    Console.WriteLine($"The measurement value is {value}");
}
```

You can nest `if` statements to check multiple conditions, as the following example shows:

```

DisplayCharacter('f'); // Output: A lowercase letter: f
DisplayCharacter('R'); // Output: An uppercase letter: R
DisplayCharacter('8'); // Output: A digit: 8
DisplayCharacter(','); // Output: Not alphanumeric character: ,

void DisplayCharacter(char ch)
{
    if (char.IsUpper(ch))
    {
        Console.WriteLine($"An uppercase letter: {ch}");
    }
    else if (char.IsLower(ch))
    {
        Console.WriteLine($"A lowercase letter: {ch}");
    }
    else if (char.IsDigit(ch))
    {
        Console.WriteLine($"A digit: {ch}");
    }
    else
    {
        Console.WriteLine($"Not alphanumeric character: {ch}");
    }
}

```

In an expression context, you can use the [conditional operator](#) `?:` to evaluate one of the two expressions based on the value of a Boolean expression.

The `switch` statement

The `switch` statement selects a statement list to execute based on a pattern match with a match expression, as the following example shows:

```

DisplayMeasurement(-4); // Output: Measured value is -4; too low.
DisplayMeasurement(5); // Output: Measured value is 5.
DisplayMeasurement(30); // Output: Measured value is 30; too high.
DisplayMeasurement(double.NaN); // Output: Failed measurement.

void DisplayMeasurement(double measurement)
{
    switch (measurement)
    {
        case < 0.0:
            Console.WriteLine($"Measured value is {measurement}; too low.");
            break;

        case > 15.0:
            Console.WriteLine($"Measured value is {measurement}; too high.");
            break;

        case double.NaN:
            Console.WriteLine("Failed measurement.");
            break;

        default:
            Console.WriteLine($"Measured value is {measurement}.");
            break;
    }
}

```

At the preceding example, the `switch` statement uses the following patterns:

- A [relational pattern](#): to compare an expression result with a constant.
- A [constant pattern](#): to test if an expression result equals a constant.

IMPORTANT

For information about the patterns supported by the `switch` statement, see [Patterns](#).

The preceding example also demonstrates the `default` case. The `default` case specifies statements to execute when a match expression doesn't match any other case pattern. If a match expression doesn't match any case pattern and there is no `default` case, control falls through a `switch` statement.

A `switch` statement executes the *statement list* in the first *switch section* whose *case pattern* matches a match expression and whose [case guard](#), if present, evaluates to `true`. A `switch` statement evaluates case patterns in text order from top to bottom. The compiler generates an error when a `switch` statement contains an unreachable case. That is a case that is already handled by an upper case or whose pattern is impossible to match.

NOTE

The `default` case can appear in any place within a `switch` statement. Regardless of its position, the `default` case is always evaluated last and only if all other case patterns aren't matched.

You can specify multiple case patterns for one section of a `switch` statement, as the following example shows:

```
DisplayMeasurement(-4); // Output: Measured value is -4; out of an acceptable range.
DisplayMeasurement(50); // Output: Measured value is 50.
DisplayMeasurement(132); // Output: Measured value is 132; out of an acceptable range.

void DisplayMeasurement(int measurement)
{
    switch (measurement)
    {
        case < 0:
        case > 100:
            Console.WriteLine($"Measured value is {measurement}; out of an acceptable range.");
            break;

        default:
            Console.WriteLine($"Measured value is {measurement}.");
            break;
    }
}
```

Within a `switch` statement, control cannot fall through from one switch section to the next. As the examples in this section show, typically you use the `break` statement at the end of each switch section to pass control out of a `switch` statement. You can also use the [return](#) and [throw](#) statements to pass control out of a `switch` statement. To imitate the fall-through behavior and pass control to other switch section, you can use the [goto statement](#).

In an expression context, you can use the [switch expression](#) to evaluate a single expression from a list of candidate expressions based on a pattern match with an expression.

Case guards

A case pattern may be not expressive enough to specify the condition for the execution of the switch section. In such a case, you can use a *case guard*. That is an additional condition that must be satisfied together with a matched pattern. A case guard must be a Boolean expression. You specify a case guard after the `when` keyword

that follows a pattern, as the following example shows:

```
DisplayMeasurements(3, 4); // Output: First measurement is 3, second measurement is 4.
DisplayMeasurements(5, 5); // Output: Both measurements are valid and equal to 5.

void DisplayMeasurements(int a, int b)
{
    switch ((a, b))
    {
        case (> 0, > 0) when a == b:
            Console.WriteLine($"Both measurements are valid and equal to {a}.");
            break;

        case (> 0, > 0):
            Console.WriteLine($"First measurement is {a}, second measurement is {b}.");
            break;

        default:
            Console.WriteLine("One or both measurements are not valid.");
            break;
    }
}
```

The preceding example uses [positional patterns](#) with nested [relational patterns](#).

Language version support

The `switch` statement supports pattern matching beginning with C# 7.0.

In C# 6 and earlier, you use the `switch` statement with the following limitations:

- A match expression must be of one of the following types: [char](#), [string](#), [bool](#), an [integral numeric](#) type, or an [enum](#) type.
- Only constant expressions are allowed in `case` labels.

C# language specification

For more information, see the following sections of the [C# language specification](#):

- [The `if` statement](#)
- [The `switch` statement](#)

For more information about features introduced in C# 7.0 and later, see the following feature proposal notes:

- [Switch statement \(Pattern matching for C# 7.0\)](#)

Jump statements (C# reference)

12/28/2021 • 5 minutes to read • [Edit Online](#)

The following statements unconditionally transfer control:

- The `break` statement: terminates the closest enclosing [iteration statement](#) or `switch` statement.
- The `continue` statement: starts a new iteration of the closest enclosing [iteration statement](#).
- The `return` statement: terminates execution of the function in which it appears and returns control to the caller.
- The `goto` statement: transfers control to a statement that is marked by a label.

For information about the `throw` statement that throws an exception and unconditionally transfers control as well, see [throw](#).

The `break` statement

The `break` statement terminates the closest enclosing [iteration statement](#) (that is, `for`, `foreach`, `while`, or `do` loop) or `switch` statement. The `break` statement transfers control to the statement that follows the terminated statement, if any.

```
int[] numbers = { 0, 1, 2, 3, 4, 5, 6, 7, 8, 9 };
foreach (int number in numbers)
{
    if (number == 3)
    {
        break;
    }

    Console.Write($"{number} ");
}
Console.WriteLine();
Console.WriteLine("End of the example.");
// Output:
// 0 1 2
// End of the example.
```

In nested loops, the `break` statement terminates only the innermost loop that contains it, as the following example shows:

```

for (int outer = 0; outer < 5; outer++)
{
    for (int inner = 0; inner < 5; inner++)
    {
        if (inner > outer)
        {
            break;
        }

        Console.Write($"{inner} ");
    }
    Console.WriteLine();
}
// Output:
// 0
// 0 1
// 0 1 2
// 0 1 2 3
// 0 1 2 3 4

```

When you use the `switch` statement inside a loop, a `break` statement at the end of a switch section transfers control only out of the `switch` statement. The loop that contains the `switch` statement is unaffected, as the following example shows:

```

double[] measurements = { -4, 5, 30, double.NaN };
foreach (double measurement in measurements)
{
    switch (measurement)
    {
        case < 0.0:
            Console.WriteLine($"Measured value is {measurement}; too low.");
            break;

        case > 15.0:
            Console.WriteLine($"Measured value is {measurement}; too high.");
            break;

        case double.NaN:
            Console.WriteLine("Failed measurement.");
            break;

        default:
            Console.WriteLine($"Measured value is {measurement}.");
            break;
    }
}
// Output:
// Measured value is -4; too low.
// Measured value is 5.
// Measured value is 30; too high.
// Failed measurement.

```

The `continue` statement

The `continue` statement starts a new iteration of the closest enclosing [iteration statement](#) (that is, `for`, `foreach`, `while`, or `do` loop), as the following example shows:

```

for (int i = 0; i < 5; i++)
{
    Console.WriteLine($"Iteration {i}: ");

    if (i < 3)
    {
        Console.WriteLine("skip");
        continue;
    }

    Console.WriteLine("done");
}
// Output:
// Iteration 0: skip
// Iteration 1: skip
// Iteration 2: skip
// Iteration 3: done
// Iteration 4: done

```

The `return` statement

The `return` statement terminates execution of the function in which it appears and returns control and the function's result, if any, to the caller.

If a function member doesn't compute a value, you use the `return` statement without expression, as the following example shows:

```

Console.WriteLine("First call:");
DisplayIfNecessary(6);

Console.WriteLine("Second call:");
DisplayIfNecessary(5);

void DisplayIfNecessary(int number)
{
    if (number % 2 == 0)
    {
        return;
    }

    Console.WriteLine(number);
}
// Output:
// First call:
// Second call:
// 5

```

As the preceding example shows, you typically use the `return` statement without expression to terminate a function member early. If a function member doesn't contain the `return` statement, it terminates after its last statement is executed.

If a function member computes a value, you use the `return` statement with an expression, as the following example shows:

```
double surfaceArea = CalculateCylinderSurfaceArea(1, 1);
Console.WriteLine($"{surfaceArea:F2}"); // output: 12.57

double CalculateCylinderSurfaceArea(double baseRadius, double height)
{
    double baseArea = Math.PI * baseRadius * baseRadius;
    double sideArea = 2 * Math.PI * baseRadius * height;
    return 2 * baseArea + sideArea;
}
```

When the `return` statement has an expression, that expression must be implicitly convertible to the return type of a function member unless it's `async`. In the case of an `async` function, the expression must be implicitly convertible to the type argument of `Task<TResult>` or `ValueTask<TResult>`, whichever is the return type of the function. If the return type of an `async` function is `Task` or `ValueTask`, you use the `return` statement without expression.

By default, the `return` statement returns the value of an expression. Beginning with C# 7.0, you can return a reference to a variable. To do that, use the `return` statement with the `ref` keyword, as the following example shows:

```
var xs = new int[] { 10, 20, 30, 40 };
ref int found = ref FindFirst(xs, s => s == 30);
found = 0;
Console.WriteLine(string.Join(" ", xs)); // output: 10 20 0 40

ref int FindFirst(int[] numbers, Func<int, bool> predicate)
{
    for (int i = 0; i < numbers.Length; i++)
    {
        if (predicate(numbers[i]))
        {
            return ref numbers[i];
        }
    }
    throw new InvalidOperationException("No element satisfies the given condition.");
}
```

For more information about ref returns, see [Ref returns and ref locals](#).

The `goto` statement

The `goto` statement transfers control to a statement that is marked by a label, as the following example shows:

```

var matrices = new Dictionary<string, int[][]>
{
    ["A"] = new[]
    {
        new[] { 1, 2, 3, 4 },
        new[] { 4, 3, 2, 1 }
    },
    ["B"] = new[]
    {
        new[] { 5, 6, 7, 8 },
        new[] { 8, 7, 6, 5 }
    },
};

CheckMatrices(matrices, 4);

void CheckMatrices(Dictionary<string, int[][]> matrixLookup, int target)
{
    foreach (var (key, matrix) in matrixLookup)
    {
        for (int row = 0; row < matrix.Length; row++)
        {
            for (int col = 0; col < matrix[row].Length; col++)
            {
                if (matrix[row][col] == target)
                {
                    goto Found;
                }
            }
        }
        Console.WriteLine($"Not found {target} in matrix {key}.");
        continue;

    Found:
        Console.WriteLine($"Found {target} in matrix {key}.");
    }
}

// Output:
// Found 4 in matrix A.
// Not found 4 in matrix B.

```

As the preceding example shows, you can use the `goto` statement to get out of a nested loop.

TIP

When you work with nested loops, consider refactoring separate loops into separate methods. That may lead to a simpler, more readable code without the `goto` statement.

You can also use the `goto` statement in the `switch statement` to transfer control to a switch section with a constant case label, as the following example shows:

```

using System;

public enum CoffeChoice
{
    Plain,
    WithMilk,
    WithIceCream,
}

public class GotoInSwitchExample
{
    public static void Main()
    {
        Console.WriteLine(CalculatePrice(CoffeChoice.Plain)); // output: 10.0
        Console.WriteLine(CalculatePrice(CoffeChoice.WithMilk)); // output: 15.0
        Console.WriteLine(CalculatePrice(CoffeChoice.WithIceCream)); // output: 17.0
    }

    private static decimal CalculatePrice(CoffeChoice choice)
    {
        decimal price = 0;
        switch (choice)
        {
            case CoffeChoice.Plain:
                price += 10.0m;
                break;

            case CoffeChoice.WithMilk:
                price += 5.0m;
                goto case CoffeChoice.Plain;

            case CoffeChoice.WithIceCream:
                price += 7.0m;
                goto case CoffeChoice.Plain;
        }
        return price;
    }
}

```

Within the `switch` statement, you can also use the statement `goto default;` to transfer control to the switch section with the `default` label.

If a label with the given name doesn't exist in the current function member, or if the `goto` statement is not within the scope of the label, a compile-time error occurs. That is, you can't use the `goto` statement to transfer control out of the current function member or into any nested scope, for example, a `try` block.

C# language specification

For more information, see the following sections of the [C# language specification](#):

- [The `break` statement](#)
- [The `continue` statement](#)
- [The `return` statement](#)

lock statement (C# reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `lock` statement acquires the mutual-exclusion lock for a given object, executes a statement block, and then releases the lock. While a lock is held, the thread that holds the lock can again acquire and release the lock. Any other thread is blocked from acquiring the lock and waits until the lock is released.

The `lock` statement is of the form

```
lock (x)
{
    // Your code...
}
```

where `x` is an expression of a [reference type](#). It's precisely equivalent to

```
object __lockObj = x;
bool __lockWasTaken = false;
try
{
    System.Threading.Monitor.Enter(__lockObj, ref __lockWasTaken);
    // Your code...
}
finally
{
    if (__lockWasTaken) System.Threading.Monitor.Exit(__lockObj);
}
```

Since the code uses a [try...finally](#) block, the lock is released even if an exception is thrown within the body of a `lock` statement.

You can't use the [await operator](#) in the body of a `lock` statement.

Guidelines

When you synchronize thread access to a shared resource, lock on a dedicated object instance (for example, `private readonly object balanceLock = new object();`) or another instance that is unlikely to be used as a lock object by unrelated parts of the code. Avoid using the same lock object instance for different shared resources, as it might result in deadlock or lock contention. In particular, avoid using the following as lock objects:

- `this`, as it might be used by the callers as a lock.
- [Type](#) instances, as those might be obtained by the [typeof](#) operator or reflection.
- string instances, including string literals, as those might be [interned](#).

Hold a lock for as short time as possible to reduce lock contention.

Example

The following example defines an `Account` class that synchronizes access to its private `balance` field by locking on a dedicated `balanceLock` instance. Using the same instance for locking ensures that the `balance` field cannot be updated simultaneously by two threads attempting to call the `Debit` or `Credit` methods simultaneously.

```

using System;
using System.Threading.Tasks;

public class Account
{
    private readonly object balanceLock = new object();
    private decimal balance;

    public Account(decimal initialBalance) => balance = initialBalance;

    public decimal Debit(decimal amount)
    {
        if (amount < 0)
        {
            throw new ArgumentOutOfRangeException(nameof(amount), "The debit amount cannot be negative.");
        }

        decimal appliedAmount = 0;
        lock (balanceLock)
        {
            if (balance >= amount)
            {
                balance -= amount;
                appliedAmount = amount;
            }
        }
        return appliedAmount;
    }

    public void Credit(decimal amount)
    {
        if (amount < 0)
        {
            throw new ArgumentOutOfRangeException(nameof(amount), "The credit amount cannot be negative.");
        }

        lock (balanceLock)
        {
            balance += amount;
        }
    }

    public decimal GetBalance()
    {
        lock (balanceLock)
        {
            return balance;
        }
    }
}

class AccountTest
{
    static async Task Main()
    {
        var account = new Account(1000);
        var tasks = new Task[100];
        for (int i = 0; i < tasks.Length; i++)
        {
            tasks[i] = Task.Run(() => Update(account));
        }
        await Task.WhenAll(tasks);
        Console.WriteLine($"Account's balance is {account.GetBalance()}");
        // Output:
        // Account's balance is 2000
    }

    static void Update(Account account)
    {

```

```
decimal[] amounts = { 0, 2, -3, 6, -2, -1, 8, -5, 11, -6 };
foreach (var amount in amounts)
{
    if (amount >= 0)
    {
        account.Credit(amount);
    }
    else
    {
        account.Debit(Math.Abs(amount));
    }
}
}
```

C# Special Characters

12/28/2021 • 2 minutes to read • [Edit Online](#)

Special characters are predefined, contextual characters that modify the program element (a literal string, an identifier, or an attribute name) to which they are prepended. C# supports the following special characters:

- `@`, the verbatim identifier character.
- `$`, the interpolated string character.

This section only includes those tokens that are not operators. See the [operators](#) section for all operators.

See also

- [C# Reference](#)
- [C# Programming Guide](#)

\$ - string interpolation (C# reference)

12/28/2021 • 5 minutes to read • [Edit Online](#)

The `$` special character identifies a string literal as an *interpolated string*. An interpolated string is a string literal that might contain *interpolation expressions*. When an interpolated string is resolved to a result string, items with interpolation expressions are replaced by the string representations of the expression results. This feature is available starting with C# 6.

String interpolation provides a more readable, convenient syntax to format strings. It's easier to read than [string composite formatting](#). Compare the following example that uses both features to produce the same output:

```
string name = "Mark";
var date = DateTime.Now;

// Composite formatting:
Console.WriteLine("Hello, {0}! Today is {1}, it's {2:HH:mm} now.", name, date.DayOfWeek, date);
// String interpolation:
Console.WriteLine($"Hello, {name}! Today is {date.DayOfWeek}, it's {date:HH:mm} now.");
// Both calls produce the same output that is similar to:
// Hello, Mark! Today is Wednesday, it's 19:40 now.
```

Structure of an interpolated string

To identify a string literal as an interpolated string, prepend it with the `$` symbol. You can't have any white space between the `$` and the `"` that starts a string literal.

The structure of an item with an interpolation expression is as follows:

```
{<interpolationExpression>[,<alignment>][:<formatString>]}
```

Elements in square brackets are optional. The following table describes each element:

ELEMENT	DESCRIPTION
<code>interpolationExpression</code>	The expression that produces a result to be formatted. String representation of <code>null</code> is String.Empty .
<code>alignment</code>	The constant expression whose value defines the minimum number of characters in the string representation of the expression result. If positive, the string representation is right-aligned; if negative, it's left-aligned. For more information, see Alignment Component .
<code>formatString</code>	A format string that is supported by the type of the expression result. For more information, see Format String Component .

The following example uses optional formatting components described above:

```

Console.WriteLine($"|{"Left",-7}|{"Right",7}|");

const int FieldWidthRightAligned = 20;
Console.WriteLine($"{Math.PI,FieldWidthRightAligned} - default formatting of the pi number");
Console.WriteLine($"{Math.PI,FieldWidthRightAligned:F3} - display only three decimal digits of the pi number");
// Expected output is:
// |Left  | Right|
//      3.14159265358979 - default formatting of the pi number
//                      3.142 - display only three decimal digits of the pi number

```

Beginning with C# 10, you can use string interpolation to initialize a constant string. All expressions used for placeholders must be constant strings. In other words, every *interpolation expression* must be a string, and it must be a compile time constant.

Special characters

To include a brace, "{" or "}", in the text produced by an interpolated string, use two braces, "{{" or "}}". For more information, see [Escaping Braces](#).

As the colon (":") has special meaning in an interpolation expression item, to use a [conditional operator](#) in an interpolation expression, enclose that expression in parentheses.

The following example shows how to include a brace in a result string. It also shows how to use a conditional operator:

```

string name = "Horace";
int age = 34;
Console.WriteLine($"He asked, \"Is your name {name}?\", but didn't wait for a reply :-{{}}");
Console.WriteLine($"{name} is {age} year{(age == 1 ? "" : "s")} old.");
// Expected output is:
// He asked, "Is your name Horace?", but didn't wait for a reply :-{
// Horace is 34 years old.

```

An interpolated verbatim string starts with the `$` character followed by the `@` character. For more information about verbatim strings, see the [string](#) and [verbatim identifier](#) articles.

NOTE

Starting with C# 8.0, you can use the `$` and `@` tokens in any order: both `@$"..."` and `@$"..."` are valid interpolated verbatim strings. In earlier C# versions, the `$` token must appear before the `@` token.

Implicit conversions and how to specify `IFormatProvider` implementation

There are three implicit conversions from an interpolated string:

1. Conversion of an interpolated string to a [String](#) instance. The string is the result of interpolated string resolution. All interpolation expression items are replaced with the properly formatted string representations of their results. This conversion uses the [CurrentCulture](#) to format expression results.
2. Conversion of an interpolated string to a [FormattableString](#) instance that represents a composite format string along with the expression results to be formatted. That allows you to create multiple result strings with culture-specific content from a single [FormattableString](#) instance. To do that, call one of the following methods:

- A [ToString\(\)](#) overload that produces a result string for the [CurrentCulture](#).
- An [Invariant](#) method that produces a result string for the [InvariantCulture](#).
- A [ToString\(IFormatProvider\)](#) method that produces a result string for a specified culture.

The [ToString\(IFormatProvider\)](#) provides a user-defined implementation of the [IFormatProvider](#) interface that supports custom formatting. For more information, see the [Custom formatting with ICustomFormatter](#) section of the [Formatting types in .NET](#) article.

3. Conversion of an interpolated string to an [IFormattable](#) instance that also allows you to create multiple result strings with culture-specific content from a single [IFormattable](#) instance.

The following example uses implicit conversion to [FormattableString](#) to create culture-specific result strings:

```
double speedOfLight = 299792.458;
FormattableString message = $"The speed of light is {speedOfLight:N3} km/s.";

System.Globalization.CultureInfo.CurrentCulture = System.Globalization.CultureInfo.GetCultureInfo("nl-NL");
string messageInCurrentCulture = message.ToString();

var specificCulture = System.Globalization.CultureInfo.GetCultureInfo("en-IN");
string messageInSpecificCulture = message.ToString(specificCulture);

string messageInInvariantCulture = FormattableString.Invariant(message);

Console.WriteLine($"{System.Globalization.CultureInfo.CurrentCulture,-10} {messageInCurrentCulture}");
Console.WriteLine($"{specificCulture,-10} {messageInSpecificCulture}");
Console.WriteLine($"{Invariant,-10} {messageInInvariantCulture}");
// Expected output is:
// nl-NL      The speed of light is 299.792,458 km/s.
// en-IN      The speed of light is 2,99,792.458 km/s.
// Invariant  The speed of light is 299,792.458 km/s.
```

Additional resources

If you're new to string interpolation, see the [String interpolation in C#](#) interactive tutorial. You can also check another [String interpolation in C#](#) tutorial. That tutorial demonstrates how to use interpolated strings to produce formatted strings.

Compilation of interpolated strings

If an interpolated string has the type `string`, it's typically transformed into a [String.Format](#) method call. The compiler may replace [String.Format](#) with [String.Concat](#) if the analyzed behavior would be equivalent to concatenation.

If an interpolated string has the type [IFormattable](#) or [FormattableString](#), the compiler generates a call to the [FormattableStringFactory.Create](#) method.

Beginning with C# 10, when an interpolated string is used, the compiler checks if the interpolated string is assigned to a type that satisfies the *interpolated string handler pattern*. An *interpolated string handler* is a custom type that converts the interpolated string into a string. An interpolated string handler is an advanced scenario, typically used for performance reasons. You can learn about the requirements to build an interpolated string handler in the language specification for [interpolated string improvements](#). You can build one following the [interpolated string handler tutorial](#) in the What's new in C# section. In .NET 6, when you use an interpolated string for an argument of type `string`, the interpolated string is processed by the [System.Runtime.CompilerServices.DefaultInterpolatedStringHandler](#).

NOTE

One side effect of interpolated string handlers is that a custom handler, including [System.Runtime.CompilerServices.DefaultInterpolatedStringHandler](#), may not evaluate all the expressions used as placeholders in the interpolated string under all conditions. That means side-effects in those expressions may not occur.

C# language specification

For more information, see the [Interpolated strings](#) section of the [C# language specification](#).

@ (C# Reference)

12/28/2021 • 2 minutes to read • [Edit Online](#)

The `@` special character serves as a verbatim identifier. It can be used in the following ways:

1. To enable C# keywords to be used as identifiers. The `@` character prefixes a code element that the compiler is to interpret as an identifier rather than a C# keyword. The following example uses the `@` character to define an identifier named `for` that it uses in a `for` loop.

```
string[] @for = { "John", "James", "Joan", "Jamie" };
for (int ctr = 0; ctr < @for.Length; ctr++)
{
    Console.WriteLine($"Here is your gift, {@for[ctr]}!");
}
// The example displays the following output:
//      Here is your gift, John!
//      Here is your gift, James!
//      Here is your gift, Joan!
//      Here is your gift, Jamie!
```

2. To indicate that a string literal is to be interpreted verbatim. The `@` character in this instance defines a *verbatim string literal*. Simple escape sequences (such as `"\"` for a backslash), hexadecimal escape sequences (such as `"\x0041"` for an uppercase A), and Unicode escape sequences (such as `"\u0041"` for an uppercase A) are interpreted literally. Only a quote escape sequence (`"\"`) is not interpreted literally; it produces one double quotation mark. Additionally, in case of a verbatim *interpolated string* brace escape sequences (`{` and `}`) are not interpreted literally; they produce single brace characters. The following example defines two identical file paths, one by using a regular string literal and the other by using a verbatim string literal. This is one of the more common uses of verbatim string literals.

```
string filename1 = @"c:\documents\files\u0066.txt";
string filename2 = "c:\\documents\\files\\u0066.txt";

Console.WriteLine(filename1);
Console.WriteLine(filename2);
// The example displays the following output:
//      c:\documents\files\u0066.txt
//      c:\documents\files\u0066.txt
```

The following example illustrates the effect of defining a regular string literal and a verbatim string literal that contain identical character sequences.

```
string s1 = "He said, \"This is the last \u0063hance\u0021\"";
string s2 = @"He said, ""This is the last \u0063hance\u0021""";

Console.WriteLine(s1);
Console.WriteLine(s2);
// The example displays the following output:
//      He said, "This is the last chance!"
//      He said, "This is the last \u0063hance\u0021"
```

3. To enable the compiler to distinguish between attributes in cases of a naming conflict. An attribute is a class that derives from `Attribute`. Its type name typically includes the suffix `Attribute`, although the compiler does not enforce this convention. The attribute can then be referenced in code either by its full

type name (for example, `[InfoAttribute]` or its shortened name (for example, `[Info]`). However, a naming conflict occurs if two shortened attribute type names are identical, and one type name includes the **Attribute** suffix but the other does not. For example, the following code fails to compile because the compiler cannot determine whether the `Info` or `InfoAttribute` attribute is applied to the `Example` class. See [CS1614](#) for more information.

```
using System;

[AttributeUsage(AttributeTargets.Class)]
public class Info : Attribute
{
    private string information;

    public Info(string info)
    {
        information = info;
    }
}

[AttributeUsage(AttributeTargets.Method)]
public class InfoAttribute : Attribute
{

Assembly level attributes interpreted by the C# compiler

12/28/2021 • 2 minutes to read • [Edit Online](#)

Most attributes are applied to specific language elements such as classes or methods; however, some attributes are global—they apply to an entire assembly or module. For example, the [AssemblyVersionAttribute](#) attribute can be used to embed version information into an assembly, like this:

```
[assembly: AssemblyVersion("1.0.0.0")]
```

Global attributes appear in the source code after any top level `using` directives and before any type, module, or namespace declarations. Global attributes can appear in multiple source files, but the files must be compiled in a single compilation pass. Visual Studio adds global attributes to the AssemblyInfo.cs file in .NET Framework projects. These attributes aren't added to .NET Core projects.

Assembly attributes are values that provide information about an assembly. They fall into the following categories:

- Assembly identity attributes
- Informational attributes
- Assembly manifest attributes

Assembly identity attributes

Three attributes (with a strong name, if applicable) determine the identity of an assembly: name, version, and culture. These attributes form the full name of the assembly and are required when you reference it in code. You can set an assembly's version and culture using attributes. However, the name value is set by the compiler, the Visual Studio IDE in the [Assembly Information Dialog Box](#), or the Assembly Linker (AL.exe) when the assembly is created. The assembly name is based on the assembly manifest. The [AssemblyFlagsAttribute](#) attribute specifies whether multiple copies of the assembly can coexist.

The following table shows the identity attributes.

ATTRIBUTE	PURPOSE
AssemblyVersionAttribute	Specifies the version of an assembly.
AssemblyCultureAttribute	Specifies which culture the assembly supports.
AssemblyFlagsAttribute	Specifies whether an assembly supports side-by-side execution on the same computer, in the same process, or in the same application domain.

Informational attributes

You use informational attributes to provide additional company or product information for an assembly. The following table shows the informational attributes defined in the [System.Reflection](#) namespace.

ATTRIBUTE	PURPOSE
AssemblyProductAttribute	Specifies a product name for an assembly manifest.
AssemblyTrademarkAttribute	Specifies a trademark for an assembly manifest.
AssemblyInformationalVersionAttribute	Specifies an informational version for an assembly manifest.
AssemblyCompanyAttribute	Specifies a company name for an assembly manifest.
AssemblyCopyrightAttribute	Defines a custom attribute that specifies a copyright for an assembly manifest.
AssemblyFileVersionAttribute	Sets a specific version number for the Win32 file version resource.
CLSCompliantAttribute	Indicates whether the assembly is compliant with the Common Language Specification (CLS).

Assembly manifest attributes

You can use assembly manifest attributes to provide information in the assembly manifest. The attributes include title, description, default alias, and configuration. The following table shows the assembly manifest attributes defined in the [System.Reflection](#) namespace.

ATTRIBUTE	PURPOSE
AssemblyTitleAttribute	Specifies an assembly title for an assembly manifest.
AssemblyDescriptionAttribute	Specifies an assembly description for an assembly manifest.
AssemblyConfigurationAttribute	Specifies an assembly configuration (such as retail or debug) for an assembly manifest.
AssemblyDefaultAliasAttribute	Defines a friendly default alias for an assembly manifest

Determine caller information using attributes interpreted by the C# compiler

12/28/2021 • 4 minutes to read • [Edit Online](#)

Using info attributes, you obtain information about the caller to a method. You obtain the file path of the source code, the line number in the source code, and the member name of the caller. To obtain member caller information, you use attributes that are applied to optional parameters. Each optional parameter specifies a default value. The following table lists the Caller Info attributes that are defined in the [System.Runtime.CompilerServices](#) namespace:

ATTRIBUTE	DESCRIPTION	TYPE
CallerFilePathAttribute	Full path of the source file that contains the caller. The full path is the path at compile time.	<code>String</code>
CallerLineNumberAttribute	Line number in the source file from which the method is called.	<code>Integer</code>
CallerMemberNameAttribute	Method name or property name of the caller.	<code>String</code>
CallerArgumentExpressionAttribute	String representation of the argument expression.	<code>String</code>

This information helps you with tracing and debugging, and helps you to create diagnostic tools. The following example shows how to use caller info attributes. On each call to the `TraceMessage` method, the caller information is inserted for the arguments to the optional parameters.

```
public void DoProcessing()
{
    TraceMessage("Something happened.");
}

public void TraceMessage(string message,
    [CallerMemberName] string memberName = "",
    [CallerFilePath] string sourceFilePath = "",
    [CallerLineNumber] int sourceLineNumber = 0)
{
    Trace.WriteLine("message: " + message);
    Trace.WriteLine("member name: " + memberName);
    Trace.WriteLine("source file path: " + sourceFilePath);
    Trace.WriteLine("source line number: " + sourceLineNumber);
}

// Sample Output:
// message: Something happened.
// member name: DoProcessing
// source file path: c:\Visual Studio Projects\CallerInfoCS\CallerInfoCS\Form1.cs
// source line number: 31
```

You specify an explicit default value for each optional parameter. You can't apply caller info attributes to parameters that aren't specified as optional. The caller info attributes don't make a parameter optional. Instead,

they affect the default value that's passed in when the argument is omitted. Caller info values are emitted as literals into the Intermediate Language (IL) at compile time. Unlike the results of the [StackTrace](#) property for exceptions, the results aren't affected by obfuscation. You can explicitly supply the optional arguments to control the caller information or to hide caller information.

Member names

You can use the `CallerMemberName` attribute to avoid specifying the member name as a `String` argument to the called method. By using this technique, you avoid the problem that **Rename Refactoring** doesn't change the `String` values. This benefit is especially useful for the following tasks:

- Using tracing and diagnostic routines.
- Implementing the [INotifyPropertyChanged](#) interface when binding data. This interface allows the property of an object to notify a bound control that the property has changed. The control can display the updated information. Without the `CallerMemberName` attribute, you must specify the property name as a literal.

The following chart shows the member names that are returned when you use the `CallerMemberName` attribute.

CALLS OCCUR WITHIN	MEMBER NAME RESULT
Method, property, or event	The name of the method, property, or event from which the call originated.
Constructor	The string ".ctor"
Static constructor	The string ".cctor"
Finalizer	The string "Finalize"
User-defined operators or conversions	The generated name for the member, for example, "op_Addition".
Attribute constructor	The name of the method or property to which the attribute is applied. If the attribute is any element within a member (such as a parameter, a return value, or a generic type parameter), this result is the name of the member that's associated with that element.
No containing member (for example, assembly-level or attributes that are applied to types)	The default value of the optional parameter.

Argument expressions

You use the [System.Runtime.CompilerServices.CallerArgumentExpressionAttribute](#) when you want the expression passed as an argument. Diagnostic libraries may want to provide more details about the *expressions* passed to arguments. By providing the expression that triggered the diagnostic, in addition to the parameter name, developers have more details about the condition that triggered the diagnostic. That extra information makes it easier to fix.

The following example shows how you can provide detailed information about the argument when it's invalid:

```
public static void ValidateArgument(string parameterName, bool condition,
[CallerArgumentExpression("condition")] string? message=null)
{
    if (!condition)
    {
        throw new ArgumentException($"Argument failed validation: <{message}>", parameterName);
    }
}
```

You would invoke it as shown in the following example:

```
public void Operation(Action func)
{
    Utilities.ValidateArgument(nameof(func), func is not null);
    func();
}
```

The expression used for `condition` is injected by the compiler into the `message` argument. When a developer calls `Operation` with a `null` argument, the following message is stored in the `ArgumentException`:

```
Argument failed validation: <func is not null>
```

This attribute enables you to write diagnostic utilities that provide more details. Developers can more quickly understand what changes are needed. You can also use the [CallerArgumentExpressionAttribute](#) to determine what expression was used as the receiver for extension methods. The following method samples a sequence at regular intervals. If the sequence has fewer elements than the frequency, it reports an error:

```
public static IEnumerable<T> Sample<T>(this IEnumerable<T> sequence, int frequency,
[CallerArgumentExpression("sequence")] string? message = null)
{
    if (sequence.Count() < frequency)
        throw new ArgumentException($"Expression doesn't have enough elements: {message}",
nameof(sequence));
    int i = 0;
    foreach (T item in sequence)
    {
        if (i++ % frequency == 0)
            yield return item;
    }
}
```

You could call this method as follows:

```
sample = Enumerable.Range(0, 10).Sample(100);
```

The preceding example would throw an [ArgumentException](#) whose message is the following text:

```
Expression doesn't have enough elements: Enumerable.Range(0, 10) (Parameter 'sequence')
```

Attributes for null-state static analysis interpreted by the C# compiler

12/28/2021 • 14 minutes to read • [Edit Online](#)

In a nullable enabled context, the compiler performs static analysis of code to determine the *null-state* of all reference type variables:

- *not-null*: Static analysis determines that a variable has a non-null value.
- *maybe-null*: Static analysis can't determine that a variable is assigned a non-null value.

These states enable the compiler to provide warnings when you may dereference a null value, throwing a [System.NullReferenceException](#). These attributes provide the compiler with semantic information about the *null-state* of arguments, return values, and object members based on the state of arguments and return values. The compiler provides more accurate warnings when your APIs have been properly annotated with this semantic information.

This article provides a brief description of each of the nullable reference type attributes and how to use them.

Let's start with an example. Imagine your library has the following API to retrieve a resource string. This method was originally written before C# 8.0 and nullable annotations:

```
bool TryGetMessage(string key, out string message)
{
    if (_messageMap.ContainsKey(key))
        message = _messageMap[key];
    else
        message = null;
    return message != null;
}
```

The preceding example follows the familiar `Try*` pattern in .NET. There are two reference parameters for this API: the `key` and the `message`. This API has the following rules relating to the *null-state* of these parameters:

- Callers shouldn't pass `null` as the argument for `key`.
- Callers can pass a variable whose value is `null` as the argument for `message`.
- If the `TryGetMessage` method returns `true`, the value of `message` isn't null. If the return value is `false`, the value of `message` is null.

The rule for `key` can be expressed succinctly in C# 8.0: `key` should be a non-nullable reference type. The `message` parameter is more complex. It allows a variable that is `null` as the argument, but guarantees, on success, that the `out` argument isn't `null`. For these scenarios, you need a richer vocabulary to describe the expectations. The `NotNullWhen` attribute, described below describes the *null-state* for the argument used for the `message` parameter.

NOTE

Adding these attributes gives the compiler more information about the rules for your API. When calling code is compiled in a nullable enabled context, the compiler will warn callers when they violate those rules. These attributes don't enable more checks on your implementation.

ATTRIBUTE	CATEGORY	MEANING
<code>AllowNull</code>	Precondition	A non-nullable parameter, field, or property may be null.
<code>DisallowNull</code>	Precondition	A nullable parameter, field, or property should never be null.
<code>MaybeNull</code>	Postcondition	A non-nullable parameter, field, property, or return value may be null.
<code>NotNull</code>	Postcondition	A nullable parameter, field, property, or return value will never be null.
<code>MaybeNullWhen</code>	Conditional postcondition	A non-nullable argument may be null when the method returns the specified <code>bool</code> value.
<code>NotNullWhen</code>	Conditional postcondition	A nullable argument won't be null when the method returns the specified <code>bool</code> value.
<code>NotNullIfNotNull</code>	Conditional postcondition	A return value, property, or argument isn't null if the argument for the specified parameter isn't null.
<code>MemberNotNull</code>	Method and property helper methods	The listed member won't be null when the method returns.
<code>MemberNotNullWhen</code>	Method and property helper methods	The listed member won't be null when the method returns the specified <code>bool</code> value.
<code>DoesNotReturn</code>	Unreachable code	A method or property never returns. In other words, it always throws an exception.
<code>DoesNotReturnIf</code>	Unreachable code	This method or property never returns if the associated <code>bool</code> parameter has the specified value.

The preceding descriptions are a quick reference to what each attribute does. The following sections describe the behavior and meaning of these attributes more thoroughly.

Preconditions: `AllowNull` and `DisallowNull`

Consider a read/write property that never returns `null` because it has a reasonable default value. Callers pass `null` to the set accessor when setting it to that default value. For example, consider a messaging system that asks for a screen name in a chat room. If none is provided, the system generates a random name:

```
public string ScreenName
{
    get => _screenName;
    set => _screenName = value ?? GenerateRandomScreenName();
}
private string _screenName;
```

When you compile the preceding code in a nullable oblivious context, everything is fine. Once you enable nullable reference types, the `ScreenName` property becomes a non-nullable reference. That's correct for the `get` accessor: it never returns `null`. Callers don't need to check the returned property for `null`. But now setting the property to `null` generates a warning. To support this type of code, you add the [System.Diagnostics.CodeAnalysis.AllowNullAttribute](#) to the property, as shown in the following code:

```
[AllowNull]
public string ScreenName
{
    get => _screenName;
    set => _screenName = value ?? GenerateRandomScreenName();
}
private string _screenName = GenerateRandomScreenName();
```

You may need to add a `using` directive for [System.Diagnostics.CodeAnalysis](#) to use this and other attributes discussed in this article. The attribute is applied to the property, not the `set` accessor. The `AllowNull` attribute specifies *pre-conditions*, and only applies to arguments. The `get` accessor has a return value, but no parameters. Therefore, the `AllowNull` attribute only applies to the `set` accessor.

The preceding example demonstrates what to look for when adding the `AllowNull` attribute on an argument:

1. The general contract for that variable is that it shouldn't be `null`, so you want a non-nullable reference type.
2. There are scenarios for a caller to pass `null` as the argument, though they aren't the most common usage.

Most often you'll need this attribute for properties, or `in`, `out`, and `ref` arguments. The `AllowNull` attribute is the best choice when a variable is typically non-null, but you need to allow `null` as a precondition.

Contrast that with scenarios for using `DisallowNull`: You use this attribute to specify that an argument of a nullable reference type shouldn't be `null`. Consider a property where `null` is the default value, but clients can only set it to a non-null value. Consider the following code:

```
public string ReviewComment
{
    get => _comment;
    set => _comment = value ?? throw new ArgumentNullException(nameof(value), "Cannot set to null");
}
string _comment;
```

The preceding code is the best way to express your design that the `ReviewComment` could be `null`, but can't be set to `null`. Once this code is nullable aware, you can express this concept more clearly to callers using the [System.Diagnostics.CodeAnalysis.DisallowNullAttribute](#):

```
[DisallowNull]
public string? ReviewComment
{
    get => _comment;
    set => _comment = value ?? throw new ArgumentNullException(nameof(value), "Cannot set to null");
}
string? _comment;
```

In a nullable context, the `ReviewComment` `get` accessor could return the default value of `null`. The compiler warns that it must be checked before access. Furthermore, it warns callers that, even though it could be `null`, callers shouldn't explicitly set it to `null`. The `DisallowNull` attribute also specifies a *pre-condition*, it doesn't affect the `get` accessor. You use the `DisallowNull` attribute when you observe these characteristics about:

1. The variable could be `null` in core scenarios, often when first instantiated.
2. The variable shouldn't be explicitly set to `null`.

These situations are common in code that was originally *null oblivious*. It may be that object properties are set in two distinct initialization operations. It may be that some properties are set only after some asynchronous work has completed.

The `AllowNull` and `DisallowNull` attributes enable you to specify that preconditions on variables may not match the nullable annotations on those variables. These provide more detail about the characteristics of your API. This additional information helps callers use your API correctly. Remember you specify preconditions using the following attributes:

- [AllowNull](#): A non-nullable argument may be null.
- [DisallowNull](#): A nullable argument should never be null.

Postconditions: `MaybeNull` and `NotNull`

Suppose you have a method with the following signature:

```
public Customer FindCustomer(string lastName, string firstName)
```

You've likely written a method like this to return `null` when the name sought wasn't found. The `null` clearly indicates that the record wasn't found. In this example, you'd likely change the return type from `Customer` to `Customer?`. Declaring the return value as a nullable reference type specifies the intent of this API clearly:

```
public Customer? FindCustomer(string lastName, string firstName)
```

For reasons covered under [Generics nullability](#) that technique may not produce the static analysis that matches your API. You may have a generic method that follows a similar pattern:

```
public T Find<T>(IEnumerable<T> sequence, Func<T, bool> predicate)
```

The method returns `null` when the sought item isn't found. You can clarify that the method returns `null` when an item isn't found by adding the `MaybeNull` annotation to the method return:

```
[return: MaybeNull]
public T Find<T>(IEnumerable<T> sequence, Func<T, bool> predicate)
```

The preceding code informs callers that the return value *may* actually be null. It also informs the compiler that

the method may return a `null` expression even though the type is non-nullable. When you have a generic method that returns an instance of its type parameter, `T`, you can express that it never returns `null` by using the `NotNull` attribute.

You can also specify that a return value or an argument isn't null even though the type is a nullable reference type. The following method is a helper method that throws if its first argument is `null`:

```
public static void ThrowWhenNull(object value, string valueExpression = "")
{
    if (value is null) throw new ArgumentNullException(nameof(value), valueExpression);
}
```

You could call this routine as follows:

```
public static void LogMessage(string? message)
{
    ThrowWhenNull(message, $"{nameof(message)} must not be null");

    Console.WriteLine(message.Length);
}
```

After enabling null reference types, you want to ensure that the preceding code compiles without warnings. When the method returns, the `value` parameter is guaranteed to be not null. However, it's acceptable to call `ThrowWhenNull` with a null reference. You can make `value` a nullable reference type, and add the `NotNull` post-condition to the parameter declaration:

```
public static void ThrowWhenNull([NotNull] object? value, string valueExpression = "")
{
    _ = value ?? throw new ArgumentNullException(nameof(value), valueExpression);
    // other logic elided
}
```

The preceding code expresses the existing contract clearly: Callers can pass a variable with the `null` value, but the argument is guaranteed to never be null if the method returns without throwing an exception.

You specify unconditional postconditions using the following attributes:

- **MaybeNull**: A non-nullable return value may be null.
- **NotNull**: A nullable return value will never be null.

Conditional post-conditions: `NotNullWhen`, `MaybeNullWhen`, and `NotNullIfNotNull`

You're likely familiar with the `string` method `String.IsNullOrEmpty(String)`. This method returns `true` when the argument is null or an empty string. It's a form of null-check: Callers don't need to null-check the argument if the method returns `false`. To make a method like this nullable aware, you'd set the argument to a nullable reference type, and add the `NotNullWhen` attribute:

```
bool IsNullOrEmpty([NotNullWhen(false)] string? value)
```

That informs the compiler that any code where the return value is `false` doesn't need null checks. The addition of the attribute informs the compiler's static analysis that `IsNullOrEmpty` performs the necessary null check: when it returns `false`, the argument isn't `null`.

```
string? userInput = GetUserInput();
if (!string.IsNullOrEmpty(userInput))
{
    int messageLength = userInput.Length; // no null check needed.
}
// null check needed on userInput here.
```

The [String.IsNullOrEmpty\(String\)](#) method will be annotated as shown above for .NET Core 3.0. You may have similar methods in your codebase that check the state of objects for null values. The compiler won't recognize custom null check methods, and you'll need to add the annotations yourself. When you add the attribute, the compiler's static analysis knows when the tested variable has been null checked.

Another use for these attributes is the `Try*` pattern. The postconditions for `ref` and `out` arguments are communicated through the return value. Consider this method shown earlier (in a nullable disabled context):

```
bool TryGetMessage(string key, out string message)
{
    if (_messageMap.ContainsKey(key))
        message = _messageMap[key];
    else
        message = null;
    return message != null;
}
```

The preceding method follows a typical .NET idiom: the return value indicates if `message` was set to the found value or, if no message is found, to the default value. If the method returns `true`, the value of `message` isn't null; otherwise, the method sets `message` to null.

In a nullable enabled context, You can communicate that idiom using the `NotNullWhen` attribute. When you annotate parameters for nullable reference types, make `message` a `string?` and add an attribute:

```
bool TryGetMessage(string key, [NotNullWhen(true)] out string? message)
{
    if (_messageMap.ContainsKey(key))
        message = _messageMap[key];
    else
        message = null;
    return message is not null;
}
```

In the preceding example, the value of `message` is known to be not null when `TryGetMessage` returns `true`. You should annotate similar methods in your codebase in the same way: the arguments could equal `null`, and are known to be not null when the method returns `true`.

There's one final attribute you may also need. Sometimes the null state of a return value depends on the null state of one or more arguments. These methods will return a non-null value whenever certain arguments aren't `null`. To correctly annotate these methods, you use the `NotNullIfNotNull` attribute. Consider the following method:

```
string GetTopLevelDomainFromFullUrl(string url)
```

If the `url` argument isn't null, the output isn't `null`. Once nullable references are enabled, you need to add more annotations if your API may accept a null argument. You could annotate the return type as shown in the following code:

```
string? GetTopLevelDomainFromFullUrl(string? url)
```

That also works, but will often force callers to implement extra `null` checks. The contract is that the return value would be `null` only when the argument `url` is `null`. To express that contract, you would annotate this method as shown in the following code:

```
[return: NotNullIfNotNull("url")]
string? GetTopLevelDomainFromFullUrl(string? url)
```

The return value and the argument have both been annotated with the `?` indicating that either could be `null`. The attribute further clarifies that the return value won't be null when the `url` argument isn't `null`.

You specify conditional postconditions using these attributes:

- **MaybeNullWhen**: A non-nullable argument may be null when the method returns the specified `bool` value.
- **NotNullWhen**: A nullable argument won't be null when the method returns the specified `bool` value.
- **NotNullIfNotNull**: A return value isn't null if the argument for the specified parameter isn't null.

Helper methods: `MemberNotNull` and `MemberNotNullWhen`

These attributes specify your intent when you've refactored common code from constructors into helper methods. The C# compiler analyzes constructors and field initializers to make sure that all non-nullable reference fields have been initialized before each constructor returns. However, the C# compiler doesn't track field assignments through all helper methods. The compiler issues warning `CS8618` when fields aren't initialized directly in the constructor, but rather in a helper method. You add the `MemberNotNullAttribute` to a method declaration and specify the fields that are initialized to a non-null value in the method. For example, consider the following example:

```
public class Container
{
    private string _uniqueIdentifier; // must be initialized.
    private string? _optionalMessage;

    public Container()
    {
        Helper();
    }

    public Container(string message)
    {
        Helper();
        _optionalMessage = message;
    }

    [MemberNotNull(nameof(_uniqueIdentifier))]
    private void Helper()
    {
        _uniqueIdentifier = DateTime.Now.Ticks.ToString();
    }
}
```

You can specify multiple field names as arguments to the `MemberNotNull` attribute constructor.

The `MemberNotNullWhenAttribute` has a `bool` argument. You use `MemberNotNullWhen` in situations where your helper method returns a `bool` indicating whether your helper method initialized fields.

Stop nullable analysis when called method throws

Some methods, typically exception helpers or other utility methods, always exit by throwing an exception. Or, a helper may throw an exception based on the value of a Boolean argument.

In the first case, you can add the [DoesNotReturnAttribute](#) attribute to the method declaration. The compiler's *null-state* analysis doesn't check any code in a method that follows a call to a method annotated with

`DoesNotReturn`. Consider this method:

```
[DoesNotReturn]
private void FailFast()
{
    throw new InvalidOperationException();
}

public void SetState(object containedField)
{
    if (containedField is null)
    {
        FailFast();
    }

    // containedField can't be null:
    _field = containedField;
}
```

The compiler doesn't issue any warnings after the call to `FailFast`.

In the second case, you add the [System.Diagnostics.CodeAnalysis.DoesNotReturnIfAttribute](#) attribute to a Boolean parameter of the method. You can modify the previous example as follows:

```
private void FailFastIf([DoesNotReturnIf(true)] bool isNull)
{
    if (isNull)
    {
        throw new InvalidOperationException();
    }
}

public void SetFieldState(object? containedField)
{
    FailFastIf(containedField == null);
    // No warning: containedField can't be null here:
    _field = containedField;
}
```

When the value of the argument matches the value of the `DoesNotReturnIf` constructor, the compiler doesn't perform any *null-state* analysis after that method.

Summary

IMPORTANT

The official documentation tracks the latest C# version. We are currently writing for C# 9.0. Depending on the version of C# you're using, various features may not be available. The *default* C# version for your project is based on the target framework. For more information, see [C# language versioning defaults](#).

Adding nullable reference types provides an initial vocabulary to describe your APIs expectations for variables

that could be `null`. The attributes provide a richer vocabulary to describe the null state of variables as preconditions and postconditions. These attributes more clearly describe your expectations and provide a better experience for the developers using your APIs.

As you update libraries for a nullable context, add these attributes to guide users of your APIs to the correct usage. These attributes help you fully describe the null-state of arguments and return values.

- **AllowNull**: A non-nullable field, parameter, or property may be null.
- **DisallowNull**: A nullable field, parameter, or property should never be null.
- **MaybeNull**: A non-nullable field, parameter, property, or return value may be null.
- **NotNull**: A nullable field, parameter, property, or return value will never be null.
- **MaybeNullWhen**: A non-nullable argument may be null when the method returns the specified `bool` value.
- **NotNullWhen**: A nullable argument won't be null when the method returns the specified `bool` value.
- **NotNullIfNotNull**: A parameter, property, or return value isn't null if the argument for the specified parameter isn't null.
- **DoesNotReturn**: A method or property never returns. In other words, it always throws an exception.
- **DoesNotReturnIf**: This method or property never returns if the associated `bool` parameter has the specified value.

Miscellaneous attributes interpreted by the C# compiler

12/28/2021 • 10 minutes to read • [Edit Online](#)

The attributes `Conditional`, `Obsolete`, `AttributeUsage`, `AsyncMethodBuilder`, `InterpolatedStringHandler`, and `ModuleInitializer` can be applied to elements in your code. They add semantic meaning to those elements. The compiler uses those semantic meanings to alter its output and report possible mistakes by developers using your code.

`Conditional` attribute

The `Conditional` attribute makes the execution of a method dependent on a preprocessing identifier. The `Conditional` attribute is an alias for `ConditionalAttribute`, and can be applied to a method or an attribute class.

In the following example, `Conditional` is applied to a method to enable or disable the display of program-specific diagnostic information:

```
#define TRACE_ON
using System;
using System.Diagnostics;

namespace AttributeExamples
{
    public class Trace
    {
        [Conditional("TRACE_ON")]
        public static void Msg(string msg)
        {
            Console.WriteLine(msg);
        }
    }

    public class TraceExample
    {
        public static void Main()
        {
            Trace.Msg("Now in Main...");
            Console.WriteLine("Done.");
        }
    }
}
```

If the `TRACE_ON` identifier isn't defined, the trace output isn't displayed. Explore for yourself in the interactive window.

The `Conditional` attribute is often used with the `DEBUG` identifier to enable trace and logging features for debug builds but not in release builds, as shown in the following example:

```
[Conditional("DEBUG")]
static void DebugMethod()
{
}
```

When a method marked conditional is called, the presence or absence of the specified preprocessing symbol

determines whether the compiler includes or omits calls to the method. If the symbol is defined, the call is included; otherwise, the call is omitted. A conditional method must be a method in a class or struct declaration and must have a `void` return type. Using `Conditional` is cleaner, more elegant, and less error-prone than enclosing methods inside `#if...#endif` blocks.

If a method has multiple `Conditional` attributes, compiler includes calls to the method if one or more conditional symbols are defined (the symbols are logically linked together by using the OR operator). In the following example, the presence of either `A` or `B` results in a method call:

```
[Conditional("A"), Conditional("B")]
static void DoIfAorB()
{
    // ...
}
```

Using `Conditional` with attribute classes

The `Conditional` attribute can also be applied to an attribute class definition. In the following example, the custom attribute `Documentation` will only add information to the metadata if `DEBUG` is defined.

```
[Conditional("DEBUG")]
public class DocumentationAttribute : System.Attribute
{
    string text;

    public DocumentationAttribute(string text)
    {
        this.text = text;
    }
}

class SampleClass
{
    // This attribute will only be included if DEBUG is defined.
    [Documentation("This method displays an integer.")]
    static void DoWork(int i)
    {
        System.Console.WriteLine(i.ToString());
    }
}
```

obsolete attribute

The `obsolete` attribute marks a code element as no longer recommended for use. Use of an entity marked obsolete generates a warning or an error. The `obsolete` attribute is a single-use attribute and can be applied to any entity that allows attributes. `Obsolete` is an alias for [ObsoleteAttribute](#).

In the following example, the `obsolete` attribute is applied to class `A` and to method `B.OldMethod`. Because the second argument of the attribute constructor applied to `B.OldMethod` is set to `true`, this method will cause a compiler error, whereas using class `A` will just produce a warning. Calling `B.NewMethod`, however, produces no warning or error. For example, when you use it with the previous definitions, the following code generates two warnings and one error:

```

using System;

namespace AttributeExamples
{
    [Obsolete("use class B")]
    public class A
    {
        public void Method() { }
    }

    public class B
    {
        [Obsolete("use NewMethod", true)]
        public void OldMethod() { }

        public void NewMethod() { }
    }

    public static class ObsoleteProgram
    {
        public static void Main()
        {
            // Generates 2 warnings:
            A a = new A();

            // Generate no errors or warnings:
            B b = new B();
            b.NewMethod();

            // Generates an error, compilation fails.
            // b.OldMethod();
        }
    }
}

```

The string provided as the first argument to the attribute constructor will be displayed as part of the warning or error. Two warnings for class `A` are generated: one for the declaration of the class reference, and one for the class constructor. The `Obsolete` attribute can be used without arguments, but including an explanation what to use instead is recommended.

In C# 10, you can use constant string interpolation and the `nameof` operator to ensure the names match:

```

public class B
{
    [Obsolete($"use {nameof(NewMethod)} instead", true)]
    public void OldMethod() { }

    public void NewMethod() { }
}

```

AttributeUsage attribute

The `AttributeUsage` attribute determines how a custom attribute class can be used. [AttributeUsageAttribute](#) is an attribute you apply to custom attribute definitions. The `AttributeUsage` attribute enables you to control:

- Which program elements attribute may be applied to. Unless you restrict its usage, an attribute may be applied to any of the following program elements:
 - Assembly
 - Module
 - Field

- Event
- Method
- Param
- Property
- Return
- Type
- Whether an attribute can be applied to a single program element multiple times.
- Whether attributes are inherited by derived classes.

The default settings look like the following example when applied explicitly:

```
[AttributeUsage(AttributeTargets.All,
                AllowMultiple = false,
                Inherited = true)]
class NewAttribute : Attribute { }
```

In this example, the `NewAttribute` class can be applied to any supported program element. But it can be applied only once to each entity. The attribute is inherited by derived classes when applied to a base class.

The `AllowMultiple` and `Inherited` arguments are optional, so the following code has the same effect:

```
[AttributeUsage(AttributeTargets.All)]
class NewAttribute : Attribute { }
```

The first `AttributeUsageAttribute` argument must be one or more elements of the `AttributeTargets` enumeration. Multiple target types can be linked together with the OR operator, like the following example shows:

```
[AttributeUsage(AttributeTargets.Property | AttributeTargets.Field)]
class NewPropertyOrFieldAttribute : Attribute { }
```

Beginning in C# 7.3, attributes can be applied to either the property or the backing field for an auto-implemented property. The attribute applies to the property, unless you specify the `field` specifier on the attribute. Both are shown in the following example:

```
class MyClass
{
    // Attribute attached to property:
    [NewPropertyOrField]
    public string Name { get; set; } = string.Empty;

    // Attribute attached to backing field:
    [field: NewPropertyOrField]
    public string Description { get; set; } = string.Empty;
}
```

If the `AllowMultiple` argument is `true`, then the resulting attribute can be applied more than once to a single entity, as shown in the following example:

```
[AttributeUsage(AttributeTargets.Class, AllowMultiple = true)]
class MultiUse : Attribute { }

[MultiUse]
[MultiUse]
class Class1 { }

[MultiUse, MultiUse]
class Class2 { }
```

In this case, `MultiUseAttribute` can be applied repeatedly because `AllowMultiple` is set to `true`. Both formats shown for applying multiple attributes are valid.

If `Inherited` is `false`, then the attribute isn't inherited by classes derived from an attributed class. For example:

```
[AttributeUsage(AttributeTargets.Class, Inherited = false)]
class NonInheritedAttribute : Attribute { }

[NonInherited]
class BClass { }

class DClass : BClass { }
```

In this case `NonInheritedAttribute` isn't applied to `DClass` via inheritance.

You can also use these keywords to specify where an attribute should be applied. For example, you can use the `field:` specifier to add an attribute to the backing field of an [auto-implemented property](#). Or you can use the `field:`, `property:` or `param:` specifier to apply an attribute to any of the elements generated from a positional record. For an example, see [Positional syntax for property definition](#).

`AsyncMethodBuilder` attribute

Beginning with C# 7, you add the [System.Runtime.CompilerServices.AsyncMethodBuilderAttribute](#) attribute to a type that can be an async return type. The attribute specifies the type that builds the async method implementation when the specified type is returned from an async method. The `AsyncMethodBuilder` attribute can be applied to a type that:

- Has an accessible `GetAwaiter` method.
- The object returned by the `GetAwaiter` method implements the [System.Runtime.CompilerServices.ICriticalNotifyCompletion](#) interface.

The constructor to the `AsyncMethodBuilder` attribute specifies the type of the associated builder. The builder must implement the following accessible members:

- A static `Create()` method that returns the type of the builder.
- A readable `Task` property that returns the async return type.
- A `void SetException(Exception)` method that sets the exception when a task faults.
- A `void SetResult()` or `void SetResult(T result)` method that marks the task as completed and optionally sets the task's result
- A `Start` method with the following API signature:

```
void Start<TStateMachine>(ref TStateMachine stateMachine)
    where TStateMachine : System.Runtime.CompilerServices.IAsyncStateMachine
```

- An `AwaitOnCompleted` method with the following signature:

```
public void AwaitOnCompleted<TAwaiter, TStateMachine>(ref TAwaiter awaiter, ref TStateMachine stateMachine)
    where TAwaiter : System.Runtime.CompilerServices.INotifyCompletion
    where TStateMachine : System.Runtime.CompilerServices.IAsyncStateMachine
```

- An `AwaitUnsafeOnCompleted` method with the following signature:

```
public void AwaitUnsafeOnCompleted<TAwaiter, TStateMachine>(ref TAwaiter awaiter, ref TStateMachine stateMachine)
    where TAwaiter : System.Runtime.CompilerServices.ICriticalNotifyCompletion
    where TStateMachine : System.Runtime.CompilerServices.IAsyncStateMachine
```

You can learn about async method builders by reading about the following builders supplied by .NET:

- [System.Runtime.CompilerServices.AsyncTaskMethodBuilder](#)
- [System.Runtime.CompilerServices.AsyncTaskMethodBuilder<TResult>](#)
- [System.Runtime.CompilerServices.AsyncValueTaskMethodBuilder](#)
- [System.Runtime.CompilerServices.AsyncValueTaskMethodBuilder<TResult>](#)

In C# 10 and later, the `AsyncMethodBuilder` attribute can be applied to an async method to override the builder for that type.

`InterpolatedStringHandler` and `InterpolatedStringHandlerArguments` attributes

Starting with C# 10, you use these attributes to specify that a type is an *interpolated string handler*. The .NET 6 library already includes [System.Runtime.CompilerServices.DefaultInterpolatedStringHandler](#) for scenarios where you use an interpolated string as the argument for a `string` parameter. You may have other instances where you want to control how interpolated strings are processed. You apply the [System.Runtime.CompilerServices.InterpolatedStringHandlerAttribute](#) to the type that implements your handler. You apply the [System.Runtime.CompilerServices.InterpolatedStringHandlerArgumentAttribute](#) to parameters of that type's constructor.

You can learn more about building an interpolated string handler in the C# 10 feature specification for [interpolated string improvements](#).

`ModuleInitializer` attribute

Starting with C# 9, the `ModuleInitializer` attribute marks a method that the runtime calls when the assembly loads. `ModuleInitializer` is an alias for [ModuleInitializerAttribute](#).

The `ModuleInitializer` attribute can only be applied to a method that:

- Is static.
- Is parameterless.
- Returns `void`.
- Is accessible from the containing module, that is, `internal` or `public`.

- Isn't a generic method.
- Isn't contained in a generic class.
- Isn't a local function.

The `ModuleInitializer` attribute can be applied to multiple methods. In that case, the order in which the runtime calls them is deterministic but not specified.

The following example illustrates use of multiple module initializer methods. The `Init1` and `Init2` methods run before `Main`, and each adds a string to the `Text` property. So when `Main` runs, the `Text` property already has strings from both initializer methods.

```
using System;

internal class ModuleInitializerExampleMain
{
    public static void Main()
    {
        Console.WriteLine(ModuleInitializerExampleModule.Text);
        //output: Hello from Init1! Hello from Init2!
    }
}
```

```
using System.Runtime.CompilerServices;

internal class ModuleInitializerExampleModule
{
    public static string? Text { get; set; }

    [ModuleInitializer]
    public static void Init1()
    {
        Text += "Hello from Init1! ";
    }

    [ModuleInitializer]
    public static void Init2()
    {
        Text += "Hello from Init2! ";
    }
}
```

Source code generators sometimes need to generate initialization code. Module initializers provide a standard place for that code. In most other cases, you should write a [static constructor](#) instead of a module initializer.

`SkipLocalsInit` attribute

Starting in C# 9, the `SkipLocalsInit` attribute prevents the compiler from setting the `.locals init` flag when emitting to metadata. The `SkipLocalsInit` attribute is a single-use attribute and can be applied to a method, a property, a class, a struct, an interface, or a module, but not to an assembly. `SkipLocalsInit` is an alias for [SkipLocalsInitAttribute](#).

The `.locals init` flag causes the CLR to initialize all of the local variables declared in a method to their default values. Since the compiler also makes sure that you never use a variable before assigning some value to it, `.locals init` is typically not necessary. However, the extra zero-initialization may have measurable performance impact in some scenarios, such as when you use [stackalloc](#) to allocate an array on the stack. In those cases, you can add the `SkipLocalsInit` attribute. If applied to a method directly, the attribute affects that method and all its nested functions, including lambdas and local functions. If applied to a type or module, it affects all methods nested inside. This attribute doesn't affect abstract methods, but it does affect code

generated for the implementation.

This attribute requires the [AllowUnsafeBlocks](#) compiler option. This requirement signals that in some cases code could view unassigned memory (for example, reading from uninitialized stack-allocated memory).

The following example illustrates the effect of `SkipLocalsInit` attribute on a method that uses `stackalloc`. The method displays whatever was in memory when the array of integers was allocated.

```
[SkipLocalsInit]
static void ReadUninitializedMemory()
{
    Span<int> numbers = stackalloc int[120];
    for (int i = 0; i < 120; i++)
    {
        Console.WriteLine(numbers[i]);
    }
}
// output depends on initial contents of memory, for example:
//0
//0
//0
//168
//0
//-1271631451
//32767
//38
//0
//0
//0
//38
// Remaining rows omitted for brevity.
```

To try this code yourself, set the `AllowUnsafeBlocks` compiler option in your `.csproj` file:

```
<PropertyGroup>
    ...
    <AllowUnsafeBlocks>true</AllowUnsafeBlocks>
</PropertyGroup>
```

Unsafe code, pointer types, and function pointers

12/28/2021 • 13 minutes to read • [Edit Online](#)

Most of the C# code you write is "verifiably safe code." *Verifiably safe code* means .NET tools can verify that the code is safe. In general, safe code doesn't directly access memory using pointers. It also doesn't allocate raw memory. It creates managed objects instead.

C# supports an `unsafe` context, in which you may write *unverifiable* code. In an `unsafe` context, code may use pointers, allocate and free blocks of memory, and call methods using function pointers. Unsafe code in C# isn't necessarily dangerous; it's just code whose safety cannot be verified.

Unsafe code has the following properties:

- Methods, types, and code blocks can be defined as unsafe.
- In some cases, unsafe code may increase an application's performance by removing array bounds checks.
- Unsafe code is required when you call native functions that require pointers.
- Using unsafe code introduces security and stability risks.
- The code that contains unsafe blocks must be compiled with the `AllowUnsafeBlocks` compiler option.

Pointer types

In an unsafe context, a type may be a pointer type, in addition to a value type, or a reference type. A pointer type declaration takes one of the following forms:

```
type* identifier;  
void* identifier; //allowed but not recommended
```

The type specified before the `*` in a pointer type is called the **referent type**. Only an `unmanaged type` can be a referent type.

Pointer types don't inherit from `object` and no conversions exist between pointer types and `object`. Also, boxing and unboxing don't support pointers. However, you can convert between different pointer types and between pointer types and integral types.

When you declare multiple pointers in the same declaration, you write the asterisk (`*`) together with the underlying type only. It isn't used as a prefix to each pointer name. For example:

```
int* p1, p2, p3;    // Ok  
int *p1, *p2, *p3; // Invalid in C#
```

A pointer can't point to a reference or to a `struct` that contains references, because an object reference can be garbage collected even if a pointer is pointing to it. The garbage collector doesn't keep track of whether an object is being pointed to by any pointer types.

The value of the pointer variable of type `MyType*` is the address of a variable of type `MyType`. The following are examples of pointer type declarations:

- `int* p : p` is a pointer to an integer.
- `int** p : p` is a pointer to a pointer to an integer.
- `int*[] p : p` is a single-dimensional array of pointers to integers.

- `char* p`: `p` is a pointer to a char.
- `void* p`: `p` is a pointer to an unknown type.

The pointer indirection operator `*` can be used to access the contents at the location pointed to by the pointer variable. For example, consider the following declaration:

```
int* myVariable;
```

The expression `*myVariable` denotes the `int` variable found at the address contained in `myVariable`.

There are several examples of pointers in the articles on the [fixed statement](#). The following example uses the `unsafe` keyword and the `fixed` statement, and shows how to increment an interior pointer. You can paste this code into the Main function of a console application to run it. These examples must be compiled with the [AllowUnsafeBlocks](#) compiler option set.

```
// Normal pointer to an object.
int[] a = new int[5] { 10, 20, 30, 40, 50 };
// Must be in unsafe code to use interior pointers.
unsafe
{
    // Must pin object on heap so that it doesn't move while using interior pointers.
    fixed (int* p = &a[0])
    {
        // p is pinned as well as object, so create another pointer to show incrementing it.
        int* p2 = p;
        Console.WriteLine(*p2);
        // Incrementing p2 bumps the pointer by four bytes due to its type ...
        p2 += 1;
        Console.WriteLine(*p2);
        p2 += 1;
        Console.WriteLine(*p2);
        Console.WriteLine("-----");
        Console.WriteLine(*p);
        // Dereferencing p and incrementing changes the value of a[0] ...
        *p += 1;
        Console.WriteLine(*p);
        *p += 1;
        Console.WriteLine(*p);
    }
}

Console.WriteLine("-----");
Console.WriteLine(a[0]);

/*
Output:
10
20
30
-----
10
11
12
-----
12
*/
```

You can't apply the indirection operator to a pointer of type `void*`. However, you can use a cast to convert a void pointer to any other pointer type, and vice versa.

A pointer can be `null`. Applying the indirection operator to a null pointer causes an implementation-defined behavior.

Passing pointers between methods can cause undefined behavior. Consider a method that returns a pointer to a local variable through an `in`, `out`, or `ref` parameter or as the function result. If the pointer was set in a fixed block, the variable to which it points may no longer be fixed.

The following table lists the operators and statements that can operate on pointers in an unsafe context:

OPERATOR/STATEMENT	USE
<code>*</code>	Performs pointer indirection.
<code>-></code>	Accesses a member of a struct through a pointer.
<code>[]</code>	Indexes a pointer.
<code>&</code>	Obtains the address of a variable.
<code>++</code> and <code>--</code>	Increments and decrements pointers.
<code>+</code> and <code>-</code>	Performs pointer arithmetic.
<code>==</code> , <code>!=</code> , <code><</code> , <code>></code> , <code><=</code> , and <code>>=</code>	Compares pointers.
<code>stackalloc</code>	Allocates memory on the stack.
<code>fixed</code> statement	Temporarily fixes a variable so that its address may be found.

For more information about pointer-related operators, see [Pointer-related operators](#).

Any pointer type can be implicitly converted to a `void*` type. Any pointer type can be assigned the value `null`. Any pointer type can be explicitly converted to any other pointer type using a cast expression. You can also convert any integral type to a pointer type, or any pointer type to an integral type. These conversions require an explicit cast.

The following example converts an `int*` to a `byte*`. Notice that the pointer points to the lowest addressed byte of the variable. When you successively increment the result, up to the size of `int` (4 bytes), you can display the remaining bytes of the variable.

```

int number = 1024;

unsafe
{
    // Convert to byte:
    byte* p = (byte*)&number;

    System.Console.WriteLine("The 4 bytes of the integer:");

    // Display the 4 bytes of the int variable:
    for (int i = 0 ; i < sizeof(int) ; ++i)
    {
        System.Console.WriteLine(" {0:X2}", *p);
        // Increment the pointer:
        p++;
    }
    System.Console.WriteLine();
    System.Console.WriteLine("The value of the integer: {0}", number);

    /* Output:
        The 4 bytes of the integer: 00 04 00 00
        The value of the integer: 1024
    */
}

```

Fixed-size buffers

In C#, you can use the `fixed` statement to create a buffer with a fixed size array in a data structure. Fixed size buffers are useful when you write methods that interoperate with data sources from other languages or platforms. The fixed array can take any attributes or modifiers that are allowed for regular struct members. The only restriction is that the array type must be `bool`, `byte`, `char`, `short`, `int`, `long`, `sbyte`, `ushort`, `uint`, `ulong`, `float`, or `double`.

```
private fixed char name[30];
```

In safe code, a C# struct that contains an array doesn't contain the array elements. The struct contains a reference to the elements instead. You can embed an array of fixed size in a `struct` when it's used in an `unsafe` code block.

The size of the following `struct` doesn't depend on the number of elements in the array, since `pathName` is a reference:

```

public struct PathArray
{
    public char[] pathName;
    private int reserved;
}

```

A `struct` can contain an embedded array in unsafe code. In the following example, the `fixedBuffer` array has a fixed size. You use a `fixed` statement to establish a pointer to the first element. You access the elements of the array through this pointer. The `fixed` statement pins the `fixedBuffer` instance field to a specific location in memory.

```

internal unsafe struct Buffer
{
    public fixed char fixedBuffer[128];
}

internal unsafe class Example
{
    public Buffer buffer = default;
}

private static void AccessEmbeddedArray()
{
    var example = new Example();

    unsafe
    {
        // Pin the buffer to a fixed location in memory.
        fixed (char* charPtr = example.buffer.fixedBuffer)
        {
            *charPtr = 'A';
        }
        // Access safely through the index:
        char c = example.buffer.fixedBuffer[0];
        Console.WriteLine(c);

        // Modify through the index:
        example.buffer.fixedBuffer[0] = 'B';
        Console.WriteLine(example.buffer.fixedBuffer[0]);
    }
}

```

The size of the 128 element `char` array is 256 bytes. Fixed size `char` buffers always take 2 bytes per character, regardless of the encoding. This array size is the same even when char buffers are marshaled to API methods or structs with `CharSet = CharSet.Auto` or `CharSet = CharSet.Ansi`. For more information, see [CharSet](#).

The preceding example demonstrates accessing `fixed` fields without pinning, which is available starting with C# 7.3.

Another common fixed-size array is the `bool` array. The elements in a `bool` array are always 1 byte in size. `bool` arrays aren't appropriate for creating bit arrays or buffers.

Fixed size buffers are compiled with the [System.Runtime.CompilerServices.UnsafeValueTypeAttribute](#), which instructs the common language runtime (CLR) that a type contains an unmanaged array that can potentially overflow. Memory allocated using `stackalloc` also automatically enables buffer overrun detection features in the CLR. The previous example shows how a fixed size buffer could exist in an `unsafe struct`.

```

internal unsafe struct Buffer
{
    public fixed char fixedBuffer[128];
}

```

The compiler-generated C# for `Buffer` is attributed as follows:

```
internal struct Buffer
{
    [StructLayout(LayoutKind.Sequential, Size = 256)]
    [CompilerGenerated]
    [UnsafeValueType]
    public struct <fixedBuffer>e__FixedBuffer
    {
        public char FixedElementField;
    }

    [FixedBuffer(typeof(char), 128)]
    public <fixedBuffer>e__FixedBuffer fixedBuffer;
}
```

Fixed size buffers differ from regular arrays in the following ways:

- May only be used in an `unsafe` context.
- May only be instance fields of structs.
- They're always vectors, or one-dimensional arrays.
- The declaration should include the length, such as `fixed char id[8]`. You can't use `fixed char id[]`.

How to use pointers to copy an array of bytes

The following example uses pointers to copy bytes from one array to another.

This example uses the `unsafe` keyword, which enables you to use pointers in the `Copy` method. The `fixed` statement is used to declare pointers to the source and destination arrays. The `fixed` statement *pins* the location of the source and destination arrays in memory so that they will not be moved by garbage collection. The memory blocks for the arrays are unpinned when the `fixed` block is completed. Because the `Copy` method in this example uses the `unsafe` keyword, it must be compiled with the `AllowUnsafeBlocks` compiler option.

This example accesses the elements of both arrays using indices rather than a second unmanaged pointer. The declaration of the `pSource` and `pTarget` pointers pins the arrays. This feature is available starting with C# 7.3.

```
static unsafe void Copy(byte[] source, int sourceOffset, byte[] target,
    int targetOffset, int count)
{
    // If either array is not instantiated, you cannot complete the copy.
    if ((source == null) || (target == null))
    {
        throw new System.ArgumentException();
    }

    // If either offset, or the number of bytes to copy, is negative, you
    // cannot complete the copy.
    if ((sourceOffset < 0) || (targetOffset < 0) || (count < 0))
    {
        throw new System.ArgumentException();
    }

    // If the number of bytes from the offset to the end of the array is
    // less than the number of bytes you want to copy, you cannot complete
    // the copy.
    if ((source.Length - sourceOffset < count) ||
        (target.Length - targetOffset < count))
    {
        throw new System.ArgumentException();
    }

    // The following fixed statement pins the location of the source and
    // target objects in memory so that they will not be moved by garbage
    // collection.
```

```

// collection.
fixed (byte* pSource = source, pTarget = target)
{
    // Copy the specified number of bytes from source to target.
    for (int i = 0; i < count; i++)
    {
        pTarget[targetOffset + i] = pSource[sourceOffset + i];
    }
}

static void UnsafeCopyArrays()
{
    // Create two arrays of the same length.
    int length = 100;
    byte[] byteArray1 = new byte[length];
    byte[] byteArray2 = new byte[length];

    // Fill byteArray1 with 0 - 99.
    for (int i = 0; i < length; ++i)
    {
        byteArray1[i] = (byte)i;
    }

    // Display the first 10 elements in byteArray1.
    System.Console.WriteLine("The first 10 elements of the original are:");
    for (int i = 0; i < 10; ++i)
    {
        System.Console.Write(byteArray1[i] + " ");
    }
    System.Console.WriteLine("\n");

    // Copy the contents of byteArray1 to byteArray2.
    Copy(byteArray1, 0, byteArray2, 0, length);

    // Display the first 10 elements in the copy, byteArray2.
    System.Console.WriteLine("The first 10 elements of the copy are:");
    for (int i = 0; i < 10; ++i)
    {
        System.Console.Write(byteArray2[i] + " ");
    }
    System.Console.WriteLine("\n");

    // Copy the contents of the last 10 elements of byteArray1 to the
    // beginning of byteArray2.
    // The offset specifies where the copying begins in the source array.
    int offset = length - 10;
    Copy(byteArray1, offset, byteArray2, 0, length - offset);

    // Display the first 10 elements in the copy, byteArray2.
    System.Console.WriteLine("The first 10 elements of the copy are:");
    for (int i = 0; i < 10; ++i)
    {
        System.Console.Write(byteArray2[i] + " ");
    }
    System.Console.WriteLine("\n");
    /* Output:
        The first 10 elements of the original are:
        0 1 2 3 4 5 6 7 8 9

        The first 10 elements of the copy are:
        0 1 2 3 4 5 6 7 8 9

        The first 10 elements of the copy are:
        90 91 92 93 94 95 96 97 98 99
    */
}

```

Function pointers

C# provides `delegate` types to define safe function pointer objects. Invoking a delegate involves instantiating a type derived from `System.Delegate` and making a virtual method call to its `Invoke` method. This virtual call uses the `callvirt` IL instruction. In performance critical code paths, using the `calli` IL instruction is more efficient.

You can define a function pointer using the `delegate*` syntax. The compiler will call the function using the `calli` instruction rather than instantiating a `delegate` object and calling `Invoke`. The following code declares two methods that use a `delegate` or a `delegate*` to combine two objects of the same type. The first method uses a `System.Func<T1,T2,TResult>` delegate type. The second method uses a `delegate*` declaration with the same parameters and return type:

```
public static T Combine<T>(Func<T, T, T> combinator, T left, T right) =>
    combinator(left, right);

public static T UnsafeCombine<T>(delegate*<T, T, T> combinator, T left, T right) =>
    combinator(left, right);
```

The following code shows how you would declare a static local function and invoke the `UnsafeCombine` method using a pointer to that local function:

```
static int localMultiply(int x, int y) => x * y;
int product = UnsafeCombine(&localMultiply, 3, 4);
```

The preceding code illustrates several of the rules on the function accessed as a function pointer:

- Function pointers can only be declared in an `unsafe` context.
- Methods that take a `delegate*` (or return a `delegate*`) can only be called in an `unsafe` context.
- The `&` operator to obtain the address of a function is allowed only on `static` functions. (This rule applies to both member functions and local functions).

The syntax has parallels with declaring `delegate` types and using pointers. The `*` suffix on `delegate` indicates the declaration is a *function pointer*. The `&` when assigning a method group to a function pointer indicates the operation takes the address of the method.

You can specify the calling convention for a `delegate*` using the keywords `managed` and `unmanaged`. In addition, for `unmanaged` function pointers, you can specify the calling convention. The following declarations show examples of each. The first declaration uses the `managed` calling convention, which is the default. The next three use an `unmanaged` calling convention. Each specifies one of the ECMA 335 calling conventions: `Cdecl`, `Stdcall`, `Fastcall`, or `Thiscall`. The last declaration uses the `unmanaged` calling convention, instructing the CLR to pick the default calling convention for the platform. The CLR will choose the calling convention at run time.

```
public static T ManagedCombine<T>(delegate* managed<T, T, T> combinator, T left, T right) =>
    combinator(left, right);
public static T CDeclCombine<T>(delegate* unmanaged[Cdecl]<T, T, T> combinator, T left, T right) =>
    combinator(left, right);
public static T StdcallCombine<T>(delegate* unmanaged[Stdcall]<T, T, T> combinator, T left, T right) =>
    combinator(left, right);
public static T FastcallCombine<T>(delegate* unmanaged[Fastcall]<T, T, T> combinator, T left, T right) =>
    combinator(left, right);
public static T ThiscallCombine<T>(delegate* unmanaged[Thiscall]<T, T, T> combinator, T left, T right) =>
    combinator(left, right);
public static T UnmanagedCombine<T>(delegate* unmanaged<T, T, T> combinator, T left, T right) =>
    combinator(left, right);
```

You can learn more about function pointers in the [Function pointer](#) proposal for C# 9.0.

C# language specification

For more information, see the [Unsafe code](#) chapter of the [C# language specification](#).

C# preprocessor directives

12/28/2021 • 13 minutes to read • [Edit Online](#)

Although the compiler doesn't have a separate preprocessor, the directives described in this section are processed as if there were one. You use them to help in conditional compilation. Unlike C and C++ directives, you can't use these directives to create macros. A preprocessor directive must be the only instruction on a line.

Nullable context

The `#nullable` preprocessor directive sets the *nullable annotation context* and *nullable warning context*. This directive controls whether nullable annotations have effect, and whether nullability warnings are given. Each context is either *disabled* or *enabled*.

Both contexts can be specified at the project level (outside of C# source code). The `#nullable` directive controls the annotation and warning contexts and takes precedence over the project-level settings. A directive sets the context(s) it controls until another directive overrides it, or until the end of the source file.

The effect of the directives is as follows:

- `#nullable disable` : Sets the nullable annotation and warning contexts to *disabled*.
- `#nullable enable` : Sets the nullable annotation and warning contexts to *enabled*.
- `#nullable restore` : Restores the nullable annotation and warning contexts to project settings.
- `#nullable disable annotations` : Sets the nullable annotation context to *disabled*.
- `#nullable enable annotations` : Sets the nullable annotation context to *enabled*.
- `#nullable restore annotations` : Restores the nullable annotation context to project settings.
- `#nullable disable warnings` : Sets the nullable warning context to *disabled*.
- `#nullable enable warnings` : Sets the nullable warning context to *enabled*.
- `#nullable restore warnings` : Restores the nullable warning context to project settings.

Conditional compilation

You use four preprocessor directives to control conditional compilation:

- `#if` : Opens a conditional compilation, where code is compiled only if the specified symbol is defined.
- `#elif` : Closes the preceding conditional compilation and opens a new conditional compilation based on if the specified symbol is defined.
- `#else` : Closes the preceding conditional compilation and opens a new conditional compilation if the previous specified symbol isn't defined.
- `#endif` : Closes the preceding conditional compilation.

When the C# compiler finds an `#if` directive, followed eventually by an `#endif` directive, it compiles the code between the directives only if the specified symbol is defined. Unlike C and C++, you can't assign a numeric value to a symbol. The `#if` statement in C# is Boolean and only tests whether the symbol has been defined or not. For example:

```
#if DEBUG
    Console.WriteLine("Debug version");
#endif
```

You can use the operators `==` (equality) and `!=` (inequality) to test for the `bool` values `true` or `false`. `true` means the symbol is defined. The statement `#if DEBUG` has the same meaning as `#if (DEBUG == true)`. You can use the `&&` (and), `||` (or), and `!` (not) operators to evaluate whether multiple symbols have been defined. You can also group symbols and operators with parentheses.

`#if`, along with the `#else`, `#elif`, `#endif`, `#define`, and `#undef` directives, lets you include or exclude code based on the existence of one or more symbols. Conditional compilation can be useful when compiling code for a debug build or when compiling for a specific configuration.

A conditional directive beginning with an `#if` directive must explicitly be terminated with an `#endif` directive. `#define` lets you define a symbol. By using the symbol as the expression passed to the `#if` directive, the expression evaluates to `true`. You can also define a symbol with the `DefineConstants` compiler option. You can undefine a symbol with `#undef`. The scope of a symbol created with `#define` is the file in which it was defined. A symbol that you define with `DefineConstants` or with `#define` doesn't conflict with a variable of the same name. That is, a variable name shouldn't be passed to a preprocessor directive, and a symbol can only be evaluated by a preprocessor directive.

`#elif` lets you create a compound conditional directive. The `#elif` expression will be evaluated if neither the preceding `#if` nor any preceding, optional, `#elif` directive expressions evaluate to `true`. If an `#elif` expression evaluates to `true`, the compiler evaluates all the code between the `#elif` and the next conditional directive. For example:

```
#define VC7
//...
#if debug
    Console.WriteLine("Debug build");
#elif VC7
    Console.WriteLine("Visual Studio 7");
#endif
```

`#else` lets you create a compound conditional directive, so that, if none of the expressions in the preceding `#if` or (optional) `#elif` directives evaluate to `true`, the compiler will evaluate all code between `#else` and the next `#endif`. `#endif` (#endif) must be the next preprocessor directive after `#else`.

`#endif` specifies the end of a conditional directive, which began with the `#if` directive.

The build system is also aware of predefined preprocessor symbols representing different `target frameworks` in SDK-style projects. They're useful when creating applications that can target more than one .NET version.

TARGET FRAMEWORKS	SYMBOLS	ADDITIONAL SYMBOLS AVAILABLE IN .NET 5+ SDK
.NET Framework	NETFRAMEWORK , NET48 , NET472 , NET471 , NET47 , NET462 , NET461 , NET46 , NET452 , NET451 , NET45 , NET40 , NET35 , NET20	NET48_OR_GREATER , NET472_OR_GREATER , NET471_OR_GREATER , NET47_OR_GREATER , NET462_OR_GREATER , NET461_OR_GREATER , NET46_OR_GREATER , NET452_OR_GREATER , NET451_OR_GREATER , NET45_OR_GREATER , NET40_OR_GREATER , NET35_OR_GREATER , NET20_OR_GREATER

TARGET FRAMEWORKS	SYMBOLS	ADDITIONAL SYMBOLS AVAILABLE IN .NET 5+ SDK
.NET Standard	NETSTANDARD , NETSTANDARD2_1 , NETSTANDARD2_0 , NETSTANDARD1_6 , NETSTANDARD1_5 , NETSTANDARD1_4 , NETSTANDARD1_3 , NETSTANDARD1_2 , NETSTANDARD1_1 , NETSTANDARD1_0	NETSTANDARD2_1_OR_GREATER , NETSTANDARD2_0_OR_GREATER , NETSTANDARD1_6_OR_GREATER , NETSTANDARD1_5_OR_GREATER , NETSTANDARD1_4_OR_GREATER , NETSTANDARD1_3_OR_GREATER , NETSTANDARD1_2_OR_GREATER , NETSTANDARD1_1_OR_GREATER , NETSTANDARD1_0_OR_GREATER
.NET 5+ (and .NET Core)	NET , NET6_0 , NET6_0_ANDROID , NET6_0_IOS , NET6_0_MACOS , NET6_0_MACCATALYST , NET6_0_TVOS , NET6_0_WINDOWS , NET5_0 , NETCOREAPP , NETCOREAPP3_1 , NETCOREAPP3_0 , NETCOREAPP2_2 , NETCOREAPP2_1 , NETCOREAPP2_0 , NETCOREAPP1_1 , NETCOREAPP1_0	NET6_0_OR_GREATER , NET6_0_ANDROID_OR_GREATER , NET6_0_IOS_OR_GREATER , NET6_0_MACOS_OR_GREATER , NET6_0_MACCATALYST_OR_GREATER , NET6_0_TVOS_OR_GREATER , NET6_0_WINDOWS_OR_GREATER , NET5_0_OR_GREATER , NETCOREAPP_OR_GREATER , NETCOREAPP3_1_OR_GREATER , NETCOREAPP3_0_OR_GREATER , NETCOREAPP2_2_OR_GREATER , NETCOREAPP2_1_OR_GREATER , NETCOREAPP2_0_OR_GREATER , NETCOREAPP1_1_OR_GREATER , NETCOREAPP1_0_OR_GREATER

NOTE

- Versionless symbols are defined regardless of the version you're targeting.
- Version-specific symbols are only defined for the version you're targeting.
- The `<framework>_OR_GREATER` symbols are defined for the version you're targeting and all earlier versions. For example, if you're targeting .NET Framework 2.0, the following symbols are defined: `NET_2_0` , `NET_2_0_OR_GREATER` , `NET_1_1_OR_GREATER` , and `NET_1_0_OR_GREATER` .

NOTE

For traditional, non-SDK-style projects, you have to manually configure the conditional compilation symbols for the different target frameworks in Visual Studio via the project's properties pages.

Other predefined symbols include the `DEBUG` and `TRACE` constants. You can override the values set for the project using `#define` . The `DEBUG` symbol, for example, is automatically set depending on your build configuration properties ("Debug" or "Release" mode).

The following example shows you how to define a `MYTEST` symbol on a file and then test the values of the `MYTEST` and `DEBUG` symbols. The output of this example depends on whether you built the project on **Debug** or **Release** configuration mode.

```
#define MYTEST
using System;
public class MyClass
{
    static void Main()
    {
#if (DEBUG && !MYTEST)
        Console.WriteLine("DEBUG is defined");
#elif (!DEBUG && MYTEST)
        Console.WriteLine("MYTEST is defined");
#elif (DEBUG && MYTEST)
        Console.WriteLine("DEBUG and MYTEST are defined");
#else
        Console.WriteLine("DEBUG and MYTEST are not defined");
#endif
    }
}
```

The following example shows you how to test for different target frameworks so you can use newer APIs when possible:

```
public class MyClass
{
    static void Main()
    {
#if NET40
        WebClient _client = new WebClient();
#else
        HttpClient _client = new HttpClient();
#endif
    }
    //...
}
```

Defining symbols

You use the following two preprocessor directives to define or undefine symbols for conditional compilation:

- `#define`: Define a symbol.
- `#undef`: Undefine a symbol.

You use `#define` to define a symbol. When you use the symbol as the expression that's passed to the `#if` directive, the expression will evaluate to `true`, as the following example shows:

```
#define VERBOSE

#if VERBOSE
    Console.WriteLine("Verbose output version");
#endif
```

NOTE

The `#define` directive cannot be used to declare constant values as is typically done in C and C++. Constants in C# are best defined as static members of a class or struct. If you have several such constants, consider creating a separate "Constants" class to hold them.

Symbols can be used to specify conditions for compilation. You can test for the symbol with either `#if` or

`#elif`. You can also use the [ConditionalAttribute](#) to perform conditional compilation. You can define a symbol, but you can't assign a value to a symbol. The `#define` directive must appear in the file before you use any instructions that aren't also preprocessor directives. You can also define a symbol with the [DefineConstants](#) compiler option. You can undefine a symbol with `#undef`.

Defining regions

You can define regions of code that can be collapsed in an outline using the following two preprocessor directives:

- `#region`: Start a region.
- `#endregion`: End a region.

`#region` lets you specify a block of code that you can expand or collapse when using the [outlining](#) feature of the code editor. In longer code files, it's convenient to collapse or hide one or more regions so that you can focus on the part of the file that you're currently working on. The following example shows how to define a region:

```
#region MyClass definition
public class MyClass
{
    static void Main()
    {
    }
}
#endregion
```

A `#region` block must be terminated with an `#endregion` directive. A `#region` block can't overlap with an `#if` block. However, a `#region` block can be nested in an `#if` block, and an `#if` block can be nested in a `#region` block.

Error and warning information

You instruct the compiler to generate user-defined compiler errors and warnings, and control line information using the following directives:

- `#error`: Generate a compiler error with a specified message.
- `#warning`: Generate a compiler warning, with a specific message.
- `#line`: Change the line number printed with compiler messages.

`#error` lets you generate a [CS1029](#) user-defined error from a specific location in your code. For example:

```
#error Deprecated code in this method.
```

NOTE

The compiler treats `#error version` in a special way and reports a compiler error, CS8304, with a message containing the used compiler and language versions.

`#warning` lets you generate a [CS1030](#) level one compiler warning from a specific location in your code. For example:

```
#warning Deprecated code in this method.
```

`#line` lets you modify the compiler's line numbering and (optionally) the file name output for errors and warnings.

The following example shows how to report two warnings associated with line numbers. The `#line 200` directive forces the next line's number to be 200 (although the default is #6), and until the next `#line` directive, the filename will be reported as "Special". The `#line default` directive returns the line numbering to its default numbering, which counts the lines that were renumbered by the previous directive.

```
class MainClass
{
    static void Main()
    {
#line 200 "Special"
        int i;
        int j;
#line default
        char c;
        float f;
#line hidden // numbering not affected
        string s;
        double d;
    }
}
```

Compilation produces the following output:

```
Special(200,13): warning CS0168: The variable 'i' is declared but never used
Special(201,13): warning CS0168: The variable 'j' is declared but never used
MainClass.cs(9,14): warning CS0168: The variable 'c' is declared but never used
MainClass.cs(10,15): warning CS0168: The variable 'f' is declared but never used
MainClass.cs(12,16): warning CS0168: The variable 's' is declared but never used
MainClass.cs(13,16): warning CS0168: The variable 'd' is declared but never used
```

The `#line` directive might be used in an automated, intermediate step in the build process. For example, if lines were removed from the original source code file, but you still wanted the compiler to generate output based on the original line numbering in the file, you could remove lines and then simulate the original line numbering with `#line`.

The `#line hidden` directive hides the successive lines from the debugger, such that when the developer steps through the code, any lines between a `#line hidden` and the next `#line` directive (assuming that it isn't another `#line hidden` directive) will be stepped over. This option can also be used to allow ASP.NET to differentiate between user-defined and machine-generated code. Although ASP.NET is the primary consumer of this feature, it's likely that more source generators will make use of it.

A `#line hidden` directive doesn't affect file names or line numbers in error reporting. That is, if the compiler finds an error in a hidden block, the compiler will report the current file name and line number of the error.

The `#line filename` directive specifies the file name you want to appear in the compiler output. By default, the actual name of the source code file is used. The file name must be in double quotation marks (") and must be preceded by a line number.

Beginning with C# 10, you can use a new form of the `#line` directive:

```
#line (1, 1) - (5, 60) 10 "partial-class.g.cs"
/*34567*/int b = 0;
```

The components of this form are:

- `(1, 1)` : The start line and column for the first character on the line that follows the directive. In this example, the next line would be reported as line 1, column 1.
- `(5, 60)` : The end line and column for the marked region.
- `10` : The column offset for the `#line` directive to take effect. In this example, the 10th column would be reported as column one. That's where the declaration `int b = 0;` begins. This field is optional. If omitted, the directive takes effect on the first column.
- `"partial-class.g.cs"` : The name of the output file.

The preceding example would generate the following warning:

```
partial-class.g.cs(1,5,1,6): warning CS0219: The variable 'b' is assigned but its value is never used
```

After remapping, the variable, `b`, is on the first line, at character six.

Domain-specific languages (DSLs) typically use this format to provide a better mapping from the source file to the generated C# output. To see more examples of this format, see the [feature specification](#) in the section on examples.

Pragmas

`#pragma` gives the compiler special instructions for the compilation of the file in which it appears. The instructions must be supported by the compiler. In other words, you can't use `#pragma` to create custom preprocessing instructions.

- `#pragma warning` : Enable or disable warnings.
- `#pragma checksum` : Generate a checksum.

```
#pragma pragma-name pragma-arguments
```

Where `pragma-name` is the name of a recognized pragma and `pragma-arguments` is the pragma-specific arguments.

#pragma warning

`#pragma warning` can enable or disable certain warnings.

```
#pragma warning disable warning-list
#pragma warning restore warning-list
```

Where `warning-list` is a comma-separated list of warning numbers. The "CS" prefix is optional. When no warning numbers are specified, `disable` disables all warnings and `restore` enables all warnings.

NOTE

To find warning numbers in Visual Studio, build your project and then look for the warning numbers in the **Output** window.

The `disable` takes effect beginning on the next line of the source file. The warning is restored on the line following the `restore`. If there's no `restore` in the file, the warnings are restored to their default state at the first line of any later files in the same compilation.

```
// pragma_warning.cs
using System;

#pragma warning disable 414, CS3021
[CLSCompliant(false)]
public class C
{
    int i = 1;
    static void Main()
    {
    }
}

#pragma warning restore CS3021
[CLSCompliant(false)] // CS3021
public class D
{
    int i = 1;
    public static void F()
    {
    }
}
```

#pragma checksum

Generates checksums for source files to aid with debugging ASP.NET pages.

```
#pragma checksum "filename" "{guid}" "checksum bytes"
```

Where "filename" is the name of the file that requires monitoring for changes or updates, "{guid}" is the Globally Unique Identifier (GUID) for the hash algorithm, and "checksum_bytes" is the string of hexadecimal digits representing the bytes of the checksum. Must be an even number of hexadecimal digits. An odd number of digits results in a compile-time warning, and the directive is ignored.

The Visual Studio debugger uses a checksum to make sure that it always finds the right source. The compiler computes the checksum for a source file, and then emits the output to the program database (PDB) file. The debugger then uses the PDB to compare against the checksum that it computes for the source file.

This solution doesn't work for ASP.NET projects, because the computed checksum is for the generated source file, rather than the .aspx file. To address this problem, `#pragma checksum` provides checksum support for ASP.NET pages.

When you create an ASP.NET project in Visual C#, the generated source file contains a checksum for the .aspx file, from which the source is generated. The compiler then writes this information into the PDB file.

If the compiler doesn't find a `#pragma checksum` directive in the file, it computes the checksum and writes the value to the PDB file.

```
class TestClass
{
    static int Main()
    {
        #pragma checksum "file.cs" "{406EA660-64CF-4C82-B6F0-42D48172A799}" "ab007f1d23d9" // New checksum
    }
}
```

C# compiler options

12/28/2021 • 2 minutes to read • [Edit Online](#)

This section describes the options interpreted by the C# compiler. Options are grouped into separate articles based on what they control, for example, language features, code generation, and output. Use the table of contents to navigate amongst them.

How to set options

There are two different ways to set compiler options in .NET projects:

- ***In your *.csproj file***

You can add MSBuild properties for any compiler option in your *.csproj file in XML format. The property name is the same as the compiler option. The value of the property sets the value of the compiler option. For example, the following project file snippet sets the `LangVersion` property.

```
<PropertyGroup>
  <LangVersion>preview</LangVersion>
</PropertyGroup>
```

For more information on setting options in project files, see the article [MSBuild properties for .NET SDK Projects](#).

- ***Using the Visual Studio Property pages***

Visual Studio provides property pages to edit build properties. To learn more about them, see [Manage project and solution properties - Windows](#) or [Manage project and solution properties - Mac](#).

.NET Framework projects

IMPORTANT

This section applies to .NET Framework projects only.

In addition to the mechanisms described above, you can set compiler options using two additional methods for .NET Framework projects:

- **Command line arguments for .NET Framework projects:** .NET Framework projects use `csc.exe` instead of `dotnet build` to build projects. You can specify command line arguments to `csc.exe` for .NET Framework projects.
- **Compiled ASP.NET pages:** .NET Framework projects use a section of the `web.config` file for compiling pages. For the new build system, and ASP.NET Core projects, options are taken from the project file.

The word for some compiler options changed from `csc.exe` and .NET Framework projects to the new MSBuild system. The new syntax is used throughout this section. Both versions are listed at the top of each page. For `csc.exe`, any arguments are listed following the option and a colon. For example, the `-doc` option would be:

```
-doc:DocFile.xml
```

You can invoke the C# compiler by typing the name of its executable file (`csc.exe`) at a command prompt.

For .NET Framework projects, you can also run *csc.exe* from the command line. Every compiler option is available in two forms: **-option** and **/option**. In .NET Framework web projects, you specify options for compiling code-behind in the *web.config* file. For more information, see [<compiler> Element](#).

If you use the **Developer Command Prompt for Visual Studio** window, all the necessary environment variables are set for you. For information on how to access this tool, see [Developer Command Prompt for Visual Studio](#).

The *csc.exe* executable file is usually located in the Microsoft.NET\Framework\<Version> folder under the *Windows* directory. Its location might vary depending on the exact configuration of a particular computer. If more than one version of .NET Framework is installed on your computer, you'll find multiple versions of this file. For more information about such installations, see [How to: determine which versions of the .NET Framework are installed](#).

C# Compiler Options for language feature rules

12/28/2021 • 7 minutes to read • [Edit Online](#)

The following options control how the compiler interprets language features. The new MSBuild syntax is shown in **Bold**. The older *csc.exe* syntax is shown in `code style`.

- **CheckForOverflowUnderflow** / `-checked`: Generate overflow checks.
- **AllowUnsafeBlocks** / `-unsafe`: Allow 'unsafe' code.
- **DefineConstants** / `-define`: Define conditional compilation symbol(s).
- **LangVersion** / `-langversion`: Specify language version such as `default` (latest major version), or `latest` (latest version, including minor versions).
- **Nullable** / `-nullable`: Enable nullable context, or nullable warnings.

CheckForOverflowUnderflow

The **CheckForOverflowUnderflow** option specifies whether an integer arithmetic statement that results in a value that is outside the range of the data type causes a run-time exception.

```
<CheckForOverflowUnderflow>true</CheckForOverflowUnderflow>
```

An integer arithmetic statement that is in the scope of a `checked` or `unchecked` keyword isn't subject to the effect of the **CheckForOverflowUnderflow** option. If an integer arithmetic statement that isn't in the scope of a `checked` or `unchecked` keyword results in a value outside the range of the data type, and **CheckForOverflowUnderflow** is `true`, that statement causes an exception at run time. If **CheckForOverflowUnderflow** is `false`, that statement doesn't cause an exception at run time. The default value for this option is `false`; overflow checking is disabled.

AllowUnsafeBlocks

The **AllowUnsafeBlocks** compiler option allows code that uses the `unsafe` keyword to compile. The default value for this option is `false`, meaning unsafe code is not allowed.

```
<AllowUnsafeBlocks>true</AllowUnsafeBlocks>
```

For more information about unsafe code, see [Unsafe Code and Pointers](#).

DefineConstants

The **DefineConstants** option defines symbols in all source code files of your program.

```
<DefineConstants>name;name2</DefineConstants>
```

This option specifies the names of one or more symbols that you want to define. The **DefineConstants** option has the same effect as the `#define` preprocessor directive except that the compiler option is in effect for all files in the project. A symbol remains defined in a source file until an `#undef` directive in the source file removes the definition. When you use the `-define` option, an `#undef` directive in one file has no effect on other source code files in the project. You can use symbols created by this option with `#if`, `#else`, `#elif`, and `#endif` to compile source

files conditionally. The C# compiler itself defines no symbols or macros that you can use in your source code; all symbol definitions must be user-defined.

NOTE

The C# `#define` directive does not allow a symbol to be given a value, as in languages such as C++. For example, `#define` cannot be used to create a macro or to define a constant. If you need to define a constant, use an `enum` variable. If you want to create a C++ style macro, consider alternatives such as generics. Since macros are notoriously error-prone, C# disallows their use but provides safer alternatives.

LangVersion

Causes the compiler to accept only syntax that is included in the chosen C# language specification.

```
<LangVersion>9.0</LangVersion>
```

The following values are valid:

VALUE	MEANING
<code>preview</code>	The compiler accepts all valid language syntax from the latest preview version.
<code>latest</code>	The compiler accepts syntax from the latest released version of the compiler (including minor version).
<code>latestMajor</code> (<code>default</code>)	The compiler accepts syntax from the latest released major version of the compiler.
<code>10.0</code>	The compiler accepts only syntax that is included in C# 10 or lower.
<code>9.0</code>	The compiler accepts only syntax that is included in C# 9 or lower.
<code>8.0</code>	The compiler accepts only syntax that is included in C# 8.0 or lower.
<code>7.3</code>	The compiler accepts only syntax that is included in C# 7.3 or lower.
<code>7.2</code>	The compiler accepts only syntax that is included in C# 7.2 or lower.
<code>7.1</code>	The compiler accepts only syntax that is included in C# 7.1 or lower.
<code>7</code>	The compiler accepts only syntax that is included in C# 7.0 or lower.
<code>6</code>	The compiler accepts only syntax that is included in C# 6.0 or lower.

VALUE	MEANING
5	The compiler accepts only syntax that is included in C# 5.0 or lower.
4	The compiler accepts only syntax that is included in C# 4.0 or lower.
3	The compiler accepts only syntax that is included in C# 3.0 or lower.
ISO-2 (or 2)	The compiler accepts only syntax that is included in ISO/IEC 23270:2006 C# (2.0).
ISO-1 (or 1)	The compiler accepts only syntax that is included in ISO/IEC 23270:2003 C# (1.0/1.2).

The default language version depends on the target framework for your application and the version of the SDK or Visual Studio installed. Those rules are defined in [C# language versioning](#).

Metadata referenced by your C# application isn't subject to the **LangVersion** compiler option.

Because each version of the C# compiler contains extensions to the language specification, **LangVersion** doesn't give you the equivalent functionality of an earlier version of the compiler.

Additionally, while C# version updates generally coincide with major .NET Framework releases, the new syntax and features aren't necessarily tied to that specific framework version. While the new features definitely require a new compiler update that is also released alongside the C# revision, each specific feature has its own minimum .NET API or common language runtime requirements that may allow it to run on downlevel frameworks by including NuGet packages or other libraries.

Regardless of which **LangVersion** setting you use, use the current version of the common language runtime to create your .exe or .dll. One exception is friend assemblies and **ModuleAssemblyName**, which work under -**langversion:ISO-1**.

For other ways to specify the C# language version, see [C# language versioning](#).

For information about how to set this compiler option programmatically, see [LanguageVersion](#).

C# language specification

VERSION	LINK	DESCRIPTION

VERSION	LINK	DESCRIPTION
C# 1.0	Download DOC	C# Language Specification Version 1.0: Microsoft Corporation

Minimum SDK version needed to support all language features

The following table lists the minimum versions of the SDK with the C# compiler that supports the corresponding language version:

C# VERSION	MINIMUM SDK VERSION
C# 10	Microsoft Visual Studio/Build Tools 2022, or .NET 6 SDK
C# 9.0	Microsoft Visual Studio/Build Tools 2019, version 16.8, or .NET 5 SDK
C# 8.0	Microsoft Visual Studio/Build Tools 2019, version 16.3, or .NET Core 3.0 SDK
C# 7.3	Microsoft Visual Studio/Build Tools 2017, version 15.7
C# 7.2	Microsoft Visual Studio/Build Tools 2017, version 15.5
C# 7.1	Microsoft Visual Studio/Build Tools 2017, version 15.3
C# 7.0	Microsoft Visual Studio/Build Tools 2017
C# 6	Microsoft Visual Studio/Build Tools 2015
C# 5	Microsoft Visual Studio/Build Tools 2012 or bundled .NET Framework 4.5 compiler
C# 4	Microsoft Visual Studio/Build Tools 2010 or bundled .NET Framework 4.0 compiler
C# 3	Microsoft Visual Studio/Build Tools 2008 or bundled .NET Framework 3.5 compiler
C# 2	Microsoft Visual Studio/Build Tools 2005 or bundled .NET Framework 2.0 compiler
C# 1.0/1.2	Microsoft Visual Studio/Build Tools .NET 2002 or bundled .NET Framework 1.0 compiler

Nullable

The **Nullable** option lets you specify the nullable context. The default value for this option is `disable`.

```
<Nullable>enable</Nullable>
```

The argument must be one of `enable`, `disable`, `warnings`, or `annotations`. The `enable` argument enables the nullable context. Specifying `disable` will disable the nullable context. When providing the `warnings` argument the nullable warning context is enabled. When specifying the `annotations` argument, the nullable annotation

context is enabled.

Flow analysis is used to infer the nullability of variables within executable code. The inferred nullability of a variable is independent of the variable's declared nullability. Method calls are analyzed even when they're conditionally omitted. For instance, [Debug.Assert](#) in release mode.

Invocation of methods annotated with the following attributes will also affect flow analysis:

- Simple pre-conditions: [AllowNullAttribute](#) and [DisallowNullAttribute](#)
- Simple post-conditions: [MaybeNullAttribute](#) and [NotNullAttribute](#)
- Conditional post-conditions: [MaybeNullWhenAttribute](#) and [NotNullWhenAttribute](#)
- [DoesNotReturnIfAttribute](#) (for example, `DoesNotReturnIf(false)` for [Debug.Assert](#)) and [DoesNotReturnAttribute](#)
- [NotNullIfNotNullAttribute](#)
- Member post-conditions: [MemberNotNullAttribute\(String\)](#) and [MemberNotNullAttribute\(String\[\]\)](#)

IMPORTANT

The global nullable context does not apply for generated code files. Regardless of this setting, the nullable context is *disabled* for any source file marked as generated. There are four ways a file is marked as generated:

1. In the .editorconfig, specify `generated_code = true` in a section that applies to that file.
2. Put `<auto-generated>` or `<auto-generated/>` in a comment at the top of the file. It can be on any line in that comment, but the comment block must be the first element in the file.
3. Start the file name with *TemporaryGeneratedFile_*
4. End the file name with *.designer.cs*, *.generated.cs*, *.g.cs*, or *.g.i.cs*.

Generators can opt-in using the `#nullable` preprocessor directive.

C# Compiler Options that control compiler output

12/28/2021 • 8 minutes to read • [Edit Online](#)

The following options control compiler output generation.

MSBUILD	CSC.EXE	DESCRIPTION
DocumentationFile	<code>-doc:</code>	Generate XML doc file from <code>///</code> comments.
OutputAssembly	<code>-out:</code>	Specify the output assembly file.
PlatformTarget	<code>-platform:</code>	Specify the target platform CPU.
ProduceReferenceAssembly	<code>-refout:</code>	Generate a reference assembly.
TargetType	<code>-target:</code>	Specify the type of the output assembly.

DocumentationFile

The **DocumentationFile** option allows you to place documentation comments in an XML file. To learn more about documenting your code, see [Recommended Tags for Documentation Comments](#). The value specifies the path to the output XML file. The XML file contains the comments in the source code files of the compilation.

```
<DocumentationFile>path/to/file.xml</DocumentationFile>
```

The source code file that contains Main or top-level statements is output first into the XML. You'll often want to use the generated .xml file with [IntelliSense](#). The .xml/ filename must be the same as the assembly name. The .xml/ file must be in the same directory as the assembly. When the assembly is referenced in a Visual Studio project, the .xml/ file is found as well. For more information about generating code comments, see [Supplying Code Comments](#). Unless you compile with `<TargetType:Module>`, `file` will contain `<assembly>` and `</assembly>` tags specifying the name of the file containing the assembly manifest for the output file. For examples, see [How to use the XML documentation features](#).

NOTE

The **DocumentationFile** option applies to all files in the project. To disable warnings related to documentation comments for a specific file or section of code, use [#pragma warning](#).

This option can be used in any .NET SDK-style project. For more information, see [DocumentationFile property](#).

OutputAssembly

The **OutputAssembly** option specifies the name of the output file. The output path specifies the folder where compiler output is placed.

```
<OutputAssembly>folder</OutputAssembly>
```

Specify the full name and extension of the file you want to create. If you don't specify the name of the output file, MSBuild uses the name of the project to specify the name of the output assembly. Old style projects use the following rules:

- An .exe will take its name from the source code file that contains the `Main` method or top-level statements.
- A .dll or .netmodule will take its name from the first source code file.

Any modules produced as part of a compilation become files associated with any assembly also produced in the compilation. Use [ildasm.exe](#) to view the assembly manifest to see the associated files.

The **OutputAssembly** compiler option is required in order for an exe to be the target of a [friend assembly](#).

PlatformTarget

Specifies which version of the CLR can run the assembly.

```
<PlatformTarget>anycpu</PlatformTarget>
```

- **anycpu** (default) compiles your assembly to run on any platform. Your application runs as a 64-bit process whenever possible and falls back to 32-bit when only that mode is available.
- **anycpu32bitpreferred** compiles your assembly to run on any platform. Your application runs in 32-bit mode on systems that support both 64-bit and 32-bit applications. You can specify this option only for projects that target .NET Framework 4.5 or later.
- **ARM** compiles your assembly to run on a computer that has an Advanced RISC Machine (ARM) processor.
- **ARM64** compiles your assembly to run by the 64-bit CLR on a computer that has an Advanced RISC Machine (ARM) processor that supports the A64 instruction set.
- **x64** compiles your assembly to be run by the 64-bit CLR on a computer that supports the AMD64 or EM64T instruction set.
- **x86** compiles your assembly to be run by the 32-bit, x86-compatible CLR.
- **Itanium** compiles your assembly to be run by the 64-bit CLR on a computer with an Itanium processor.

On a 64-bit Windows operating system:

- Assemblies compiled with **x86** execute on the 32-bit CLR running under WOW64.
- A DLL compiled with the **anycpu** executes on the same CLR as the process into which it's loaded.
- Executables that are compiled with the **anycpu** execute on the 64-bit CLR.
- Executables compiled with **anycpu32bitpreferred** execute on the 32-bit CLR.

The **anycpu32bitpreferred** setting is valid only for executable (.EXE) files, and it requires .NET Framework 4.5 or later. For more information about developing an application to run on a Windows 64-bit operating system, see [64-bit Applications](#).

You set the **PlatformTarget** option from **Build** properties page for your project in Visual Studio.

The behavior of **anycpu** has some additional nuances on .NET Core and .NET 5 and later releases. When you set **anycpu**, publish your app and execute it with either the x86 `dotnet.exe` or the x64 `dotnet.exe`. For self-contained apps, the `dotnet publish` step packages the executable for the configured RID.

ProduceReferenceAssembly

The **ProduceReferenceAssembly** option specifies a file path where the reference assembly should be output.

It translates to `metadataPeStream` in the Emit API. The `filepath` specifies the path for the reference assembly. It should generally match that of the primary assembly. The recommended convention (used by MSBuild) is to place the reference assembly in a "ref/" subfolder relative to the primary assembly.

```
<ProduceReferenceAssembly>filepath</ProduceReferenceAssembly>
```

Reference assemblies are a special type of assembly that contains only the minimum amount of metadata required to represent the library's public API surface. They include declarations for all members that are significant when referencing an assembly in build tools. Reference assemblies exclude all member implementations and declarations of private members. Those members have no observable impact on their API contract. For more information, see [Reference assemblies](#) in the .NET Guide.

The `ProduceReferenceAssembly` and `ProduceOnlyReferenceAssembly` options are mutually exclusive.

TargetType

The `TargetType` compiler option can be specified in one of the following forms:

- **library**: to create a code library. **library** is the default value.
- **exe**: to create an .exe file.
- **module** to create a module.
- **winexe** to create a Windows program.
- **winmdobj** to create an intermediate *.winmdobj* file.
- **appcontainerexe** to create an .exe file for Windows 8.x Store apps.

NOTE

For .NET Framework targets, unless you specify **module**, this option causes a .NET Framework assembly manifest to be placed in an output file. For more information, see [Assemblies in .NET](#) and [Common Attributes](#).

```
<TargetType>library</TargetType>
```

The compiler creates only one assembly manifest per compilation. Information about all files in a compilation is placed in the assembly manifest. When producing multiple output files at the command line, only one assembly manifest can be created and it must go into the first output file specified on the command line.

If you create an assembly, you can indicate that all or part of your code is CLS-compliant with the [CLSCompliantAttribute](#) attribute.

library

The **library** option causes the compiler to create a dynamic-link library (DLL) rather than an executable file (EXE). The DLL will be created with the *.dll* extension. Unless otherwise specified with the [OutputAssembly](#) option, the output file name takes the name of the first input file. When building a *.dll* file, a `Main` method isn't required.

exe

The **exe** option causes the compiler to create an executable (EXE), console application. The executable file will be created with the *.exe* extension. Use **winexe** to create a Windows program executable. Unless otherwise specified with the [OutputAssembly](#) option, the output file name takes the name of the input file that contains the entry point (`Main` method or top-level statements). One and only one entry point is required in the source code files that are compiled into an *.exe* file. The [StartupObject](#) compiler option lets you specify which class contains the `Main` method, in cases where your code has more than one class with a `Main` method.

module

This option causes the compiler to not generate an assembly manifest. By default, the output file created by compiling with this option will have an extension of *.netmodule*. A file that doesn't have an assembly manifest cannot be loaded by the .NET runtime. However, such a file can be incorporated into the assembly manifest of an assembly with [AddModules](#). If more than one module is created in a single compilation, [internal](#) types in one module will be available to other modules in the compilation. When code in one module references `internal` types in another module, then both modules must be incorporated into an assembly manifest, with [AddModules](#). Creating a module isn't supported in the Visual Studio development environment.

winexe

The **winexe** option causes the compiler to create an executable (EXE), Windows program. The executable file will be created with the .exe extension. A Windows program is one that provides a user interface from either the .NET library or with the Windows APIs. Use **exe** to create a console application. Unless otherwise specified with the [OutputAssembly](#) option, the output file name takes the name of the input file that contains the `Main` method. One and only one `Main` method is required in the source code files that are compiled into an .exe file. The [StartupObject](#) option lets you specify which class contains the `Main` method, in cases where your code has more than one class with a `Main` method.

winmdobj

If you use the **winmdobj** option, the compiler creates an intermediate *.winmdobj* file that you can convert to a Windows Runtime binary (*.winmd*) file. The *.winmd* file can then be consumed by JavaScript and C++ programs, in addition to managed language programs.

The **winmdobj** setting signals to the compiler that an intermediate module is required. The *.winmdobj* file can then be fed through the [WinMDExp](#) export tool to produce a Windows metadata (*.winmd*) file. The *.winmd* file contains both the code from the original library and the WinMD metadata that is used by JavaScript or C++ and by the Windows Runtime. The output of a file that's compiled by using the **winmdobj** compiler option is used only as input for the WinMDExp export tool. The *.winmdobj* file itself isn't referenced directly. Unless you use the [OutputAssembly](#) option, the output file name takes the name of the first input file. A `Main` method isn't required.

appcontainerexe

If you use the **appcontainerexe** compiler option, the compiler creates a Windows executable (.exe) file that must be run in an app container. This option is equivalent to `-target:winexe` but is designed for Windows 8.x Store apps.

To require the app to run in an app container, this option sets a bit in the [Portable Executable](#) (PE) file. When that bit is set, an error occurs if the `CreateProcess` method tries to launch the executable file outside an app container. Unless you use the [OutputAssembly](#) option, the output file name takes the name of the input file that contains the `Main` method.

C# Compiler Options that specify inputs

12/28/2021 • 5 minutes to read • [Edit Online](#)

The following options control compiler inputs. The new MSBuild syntax is shown in **Bold**. The older *csc.exe* syntax is shown in `code style`.

- **References** / `-reference` or `-references`: Reference metadata from the specified assembly file or files.
- **AddModules** / `-addmodule`: Add a module (created with `target:module` to this assembly.)
- **EmbedInteropTypes** / `-link`: Embed metadata from the specified interop assembly files.

References

The **References** option causes the compiler to import [public](#) type information in the specified file into the current project, enabling you to reference metadata from the specified assembly files.

```
<Reference Include="filename" />
```

`filename` is the name of a file that contains an assembly manifest. To import more than one file, include a separate **Reference** element for each file. You can define an alias as a child element of the **Reference** element:

```
<Reference Include="filename.dll">  
  <Aliases>LS</Aliases>  
</Reference>
```

In the previous example, `LS` is the valid C# identifier that represents a root namespace that will contain all namespaces in the assembly *filename.dll*. The files you import must contain a manifest. Use [AdditionalLibPaths](#) to specify the directory in which one or more of your assembly references is located. The [AdditionalLibPaths](#) topic also discusses the directories in which the compiler searches for assemblies. In order for the compiler to recognize a type in an assembly, and not in a module, it needs to be forced to resolve the type, which you can do by defining an instance of the type. There are other ways to resolve type names in an assembly for the compiler: for example, if you inherit from a type in an assembly, the type name will then be recognized by the compiler. Sometimes it is necessary to reference two different versions of the same component from within one assembly. To do this, use the **Aliases** element on the **References** element for each file to distinguish between the two files. This alias will be used as a qualifier for the component name, and will resolve to the component in one of the files.

NOTE

In Visual Studio, use the **Add Reference** command. For more information, see [How to: Add or Remove References By Using the Reference Manager](#).

AddModules

This option adds a module that was created with the `<TargetType>module</TargetType>` switch to the current compilation:

```
<AddModule Include=file1 />
<AddModule Include=file2 />
```

Where `file`, `file2` are output files that contain metadata. The file can't contain an assembly manifest. To import more than one file, separate file names with either a comma or a semicolon. All modules added with **AddModules** must be in the same directory as the output file at run time. That is, you can specify a module in any directory at compile time but the module must be in the application directory at run time. If the module isn't in the application directory at run time, you'll get a [TypeLoadException](#). `file` can't contain an assembly. For example, if the output file was created with **TargetType** option of **module**, its metadata can be imported with **AddModules**.

If the output file was created with a **TargetType** option other than **module**, its metadata cannot be imported with **AddModules** but can be imported with the **References** option.

EmbedInteropTypes

Causes the compiler to make COM type information in the specified assemblies available to the project that you are currently compiling.

```
<References>
  <EmbedInteropTypes>file1;file2;file3</EmbedInteropTypes>
</References>
```

Where `file1;file2;file3` is a semicolon-delimited list of assembly file names. If the file name contains a space, enclose the name in quotation marks. The **EmbedInteropTypes** option enables you to deploy an application that has embedded type information. The application can then use types in a runtime assembly that implement the embedded type information without requiring a reference to the runtime assembly. If various versions of the runtime assembly are published, the application that contains the embedded type information can work with the various versions without having to be recompiled. For an example, see [Walkthrough: Embedding Types from Managed Assemblies](#).

Using the **EmbedInteropTypes** option is especially useful when you're working with COM interop. You can embed COM types so that your application no longer requires a primary interop assembly (PIA) on the target computer. The **EmbedInteropTypes** option instructs the compiler to embed the COM type information from the referenced interop assembly into the resulting compiled code. The COM type is identified by the CLSID (GUID) value. As a result, your application can run on a target computer that has installed the same COM types with the same CLSID values. Applications that automate Microsoft Office are a good example. Because applications like Office usually keep the same CLSID value across different versions, your application can use the referenced COM types as long as .NET Framework 4 or later is installed on the target computer and your application uses methods, properties, or events that are included in the referenced COM types. The **EmbedInteropTypes** option embeds only interfaces, structures, and delegates. Embedding COM classes isn't supported.

NOTE

When you create an instance of an embedded COM type in your code, you must create the instance by using the appropriate interface. Attempting to create an instance of an embedded COM type by using the `CoClass` causes an error.

Like the **References** compiler option, the **EmbedInteropTypes** compiler option uses the `Csc.rsp` response file, which references frequently used .NET assemblies. Use the **NoConfig** compiler option if you don't want the compiler to use the `Csc.rsp` file.

```
// The following code causes an error if ISampleInterface is an embedded interop type.  
ISampleInterface<SampleType> sample;
```

Types that have a generic parameter whose type is embedded from an interop assembly cannot be used if that type is from an external assembly. This restriction doesn't apply to interfaces. For example, consider the [Range](#) interface that is defined in the [Microsoft.Office.Interop.Excel](#) assembly. If a library embeds interop types from the [Microsoft.Office.Interop.Excel](#) assembly and exposes a method that returns a generic type that has a parameter whose type is the [Range](#) interface, that method must return a generic interface, as shown in the following code example.

```
using System;  
using System.Collections.Generic;  
using System.Linq;  
using System.Text;  
using Microsoft.Office.Interop.Excel;  
  
public class Utility  
{  
    // The following code causes an error when called by a client assembly.  
    public List<Range> GetRange1()  
    {  
        return null;  
    }  
  
    // The following code is valid for calls from a client assembly.  
    public IList<Range> GetRange2()  
    {  
        return null;  
    }  
}
```

In the following example, client code can call the method that returns the [IList](#) generic interface without error.

```
public class Client  
{  
    public void Main()  
    {  
        Utility util = new Utility();  
  
        // The following code causes an error.  
        List<Range> rangeList1 = util.GetRange1();  
  
        // The following code is valid.  
        List<Range> rangeList2 = (List<Range>)util.GetRange2();  
    }  
}
```

C# Compiler Options to report errors and warnings

12/28/2021 • 3 minutes to read • [Edit Online](#)

The following options control how the compiler reports errors and warnings. The new MSBuild syntax is shown in **Bold**. The older *csc.exe* syntax is shown in `code style`.

- **WarningLevel** / `-warn` : Set warning level.
- **TreatWarningsAsErrors** / `-warnaserror` : Treat all warnings as errors
- **WarningsAsErrors** / `-warnaserror` : Treat one or more warnings as errors
- **WarningsNotAsErrors** / `-warnnotaserror` : Treat one or more warnings not as errors
- **DisabledWarnings** / `-nowarn` : Set a list of disabled warnings.
- **CodeAnalysisRuleSet** / `-ruleset` : Specify a ruleset file that disables specific diagnostics.
- **ErrorLog** / `-errorlog` : Specify a file to log all compiler and analyzer diagnostics.
- **ReportAnalyzer** / `-reportanalyzer` : Report additional analyzer information, such as execution time.

WarningLevel

The **WarningLevel** option specifies the warning level for the compiler to display.

```
<WarningLevel>3</WarningLevel>
```

The element value is the warning level you want displayed for the compilation: Lower numbers show only high severity warnings. Higher numbers show more warnings. The value must be zero or a positive integer:

WARNING LEVEL	MEANING
0	Turns off emission of all warning messages.
1	Displays severe warning messages.
2	Displays level 1 warnings plus certain, less-severe warnings, such as warnings about hiding class members.
3	Displays level 2 warnings plus certain, less-severe warnings, such as warnings about expressions that always evaluate to <code>true</code> or <code>false</code> .
4 (the default)	Displays all level 3 warnings plus informational warnings.
5	Displays level 4 warnings plus additional warnings from the compiler shipped with C# 9.0.
Greater than 5	Any value greater than 5 will be treated as 5. To make sure you always have all warnings if the compiler is updated with new warning levels, put an arbitrary large value (for example, <code>9999</code>).

To get information about an error or warning, you can look up the error code in the Help Index. For other ways to get information about an error or warning, see [C# Compiler Errors](#). Use **TreatWarningsAsErrors** to treat all

warnings as errors. Use [DisabledWarnings](#) to disable certain warnings.

TreatWarningsAsErrors

The **TreatWarningsAsErrors** option treats all warnings as errors. You can also use the **TreatWarningsAsErrors** to set only some warnings as errors. If you turn on **TreatWarningsAsErrors**, you can use **TreatWarningsAsErrors** to list warnings that shouldn't be treated as errors.

```
<TreatWarningsAsErrors>true</TreatWarningsAsErrors>
```

All warning messages are instead reported as errors. The build process halts (no output files are built). By default, **TreatWarningsAsErrors** isn't in effect, which means warnings don't prevent the generation of an output file. Optionally, if you want only a few specific warnings to be treated as errors, you may specify a comma-separated list of warning numbers to treat as errors. The set of all nullability warnings can be specified with the [Nullable](#) shorthand. Use [WarningLevel](#) to specify the level of warnings that you want the compiler to display. Use [DisabledWarnings](#) to disable certain warnings.

WarningsAsErrors and WarningsNotAsErrors

The **WarningsAsErrors** and **WarningsNotAsErrors** options override the **TreatWarningsAsErrors** option for a list of warnings.

Enable warnings 0219 and 0168 as errors:

```
<WarningsAsErrors>0219,0168</WarningsAsErrors>
```

Disable the same warnings as errors:

```
<WarningsNotAsErrors>0219,0168</WarningsNotAsErrors>
```

You use **WarningsAsErrors** to configure a set of warnings as errors. Use **WarningsNotAsErrors** to configure a set of warnings that should not be errors when you've set all warnings as errors.

DisabledWarnings

The **DisabledWarnings** option lets you suppress the compiler from displaying one or more warnings. Separate multiple warning numbers with a comma.

```
<DisabledWarnings>number1, number2</DisabledWarnings>
```

`number1`, `number2` Warning number(s) that you want the compiler to suppress. You specify the numeric part of the warning identifier. For example, if you want to suppress *CS0028*, you could specify

`<DisabledWarnings>28</DisabledWarnings>`. The compiler silently ignores warning numbers passed to **DisabledWarnings** that were valid in previous releases, but that have been removed. For example, *CS0679* was valid in the compiler in Visual Studio .NET 2002 but was removed later.

The following warnings cannot be suppressed by the **DisabledWarnings** option:

- Compiler Warning (level 1) CS2002
- Compiler Warning (level 1) CS2023
- Compiler Warning (level 1) CS2029

CodeAnalysisRuleSet

Specify a ruleset file that configures specific diagnostics.

```
<CodeAnalysisRuleSet>MyConfiguration.ruleset</CodeAnalysisRuleSet>
```

Where `MyConfiguration.ruleset` is the path to the ruleset file. For more information on using rule sets, see the article in the [Visual Studio documentation on Rule sets](#).

ErrorLog

Specify a file to log all compiler and analyzer diagnostics.

```
<ErrorLog>compiler-diagnostics.sarif</ErrorLog>
```

The **ErrorLog** option causes the compiler to output a [Static Analysis Results Interchange Format \(SARIF\) log](#). SARIF logs are typically read by tools that analyze the results from compiler and analyzer diagnostics.

ReportAnalyzer

Report additional analyzer information, such as execution time.

```
<ReportAnalyzer>true</ReportAnalyzer>
```

The **ReportAnalyzer** option causes the compiler to emit extra MSBuild log information that details the performance characteristics of analyzers in the build. It's typically used by analyzer authors as part of validating the analyzer.

C# Compiler Options that control code generation

12/28/2021 • 4 minutes to read • [Edit Online](#)

The following options control code generation by the compiler. The new MSBuild syntax is shown in **Bold**. The older *csc.exe* syntax is shown in `code style`.

- **DebugType** / `-debug`: Emit (or don't emit) debugging information.
- **Optimize** / `-optimize`: Enable optimizations.
- **Deterministic** / `-deterministic`: Produce byte-for-byte equivalent output from the same input source.
- **ProduceOnlyReferenceAssembly** / `-refonly`: Produce a reference assembly, instead of a full assembly, as the primary output.

DebugType

The **DebugType** option causes the compiler to generate debugging information and place it in the output file or files. Debugging information is added by default for the *Debug* build configuration. It is off by default for the *Release* build configuration.

```
<DebugType>pdbonly</DebugType>
```

For all compiler versions starting with C# 6.0, there is no difference between *pdbonly* and *full*. Choose *pdbonly*. To change the location of the *.pdb* file, see [PdbFile](#).

The following values are valid:

VALUE	MEANING
<code>full</code>	Emit debugging information to <i>.pdb</i> file using default format for the current platform: Windows: A Windows pdb file. Linux/macOS: A Portable PDB file.
<code>pdbonly</code>	Same as <code>full</code> . See the note below for more information.
<code>portable</code>	Emit debugging information to <i>.pdb</i> file using cross-platform Portable PDB format.
<code>embedded</code>	Emit debugging information into the <i>.dll/.exe</i> itself (<i>.pdb</i> file is not produced) using Portable PDB format.

IMPORTANT

The following information applies only to compilers older than C# 6.0. The value of this element can be either `full` or `pdbonly`. The *full* argument, which is in effect if you don't specify *pdbonly*, enables attaching a debugger to the running program. Specifying *pdbonly* allows source code debugging when the program is started in the debugger but will only display assembler when the running program is attached to the debugger. Use this option to create debug builds. If you use *Full*, be aware that there's some impact on the speed and size of JIT optimized code and a small impact on code quality with *full*. We recommend *pdbonly* or no PDB for generating release code. One difference between *pdbonly* and *full* is that with *full* the compiler emits a [DebuggableAttribute](#), which is used to tell the JIT compiler that debug information is available. Therefore, you will get an error if your code contains the [DebuggableAttribute](#) set to false if you use *full*. For more information on how to configure the debug performance of an application, see [Making an Image Easier to Debug](#).

Optimize

The **Optimize** option enables or disables optimizations performed by the compiler to make your output file smaller, faster, and more efficient. The *Optimize* option is enabled by default for a *Release* build configuration. It is off by default for a *Debug* build configuration.

```
<Optimize>true</Optimize>
```

You set the **Optimize** option from **Build** properties page for your project in Visual Studio.

Optimize also tells the common language runtime to optimize code at run time. By default, optimizations are disabled. Specify **Optimize+** to enable optimizations. When building a module to be used by an assembly, use the same **Optimize** settings as used by the assembly. It's possible to combine the **Optimize** and [Debug](#) options.

Deterministic

Causes the compiler to produce an assembly whose byte-for-byte output is identical across compilations for identical inputs.

```
<Deterministic>true</Deterministic>
```

By default, compiler output from a given set of inputs is unique, since the compiler adds a timestamp and an MVID that is generated from random numbers. You use the `<Deterministic>` option to produce a *deterministic assembly*, one whose binary content is identical across compilations as long as the input remains the same. In such a build, the timestamp and MVID fields will be replaced with values derived from a hash of all the compilation inputs. The compiler considers the following inputs that affect determinism:

- The sequence of command-line parameters.
- The contents of the compiler's .rsp response file.
- The precise version of the compiler used, and its referenced assemblies.
- The current directory path.
- The binary contents of all files explicitly passed to the compiler either directly or indirectly, including:
 - Source files
 - Referenced assemblies
 - Referenced modules
 - Resources
 - The strong name key file
 - @ response files

- Analyzers
- Rulesets
- Other files that may be used by analyzers
- The current culture (for the language in which diagnostics and exception messages are produced).
- The default encoding (or the current code page) if the encoding isn't specified.
- The existence, non-existence, and contents of files on the compiler's search paths (specified, for example, by `-lib` or `-recurse`).
- The Common Language Runtime (CLR) platform on which the compiler is run.
- The value of `%LIBPATH%`, which can affect analyzer dependency loading.

Deterministic compilation can be used for establishing whether a binary is compiled from a trusted source. Deterministic output can be useful when the source is publicly available. It can also determine whether build steps that are dependent on changes to binary used in the build process.

ProduceOnlyReferenceAssembly

The **ProduceOnlyReferenceAssembly** option indicates that a reference assembly should be output instead of an implementation assembly, as the primary output. The **ProduceOnlyReferenceAssembly** parameter silently disables outputting PDBs, as reference assemblies cannot be executed.

```
<ProduceOnlyReferenceAssembly>true</ProduceOnlyReferenceAssembly>
```

Reference assemblies are a special type of assembly. Reference assemblies contain only the minimum amount of metadata required to represent the library's public API surface. They include declarations for all members that are significant when referencing an assembly in build tools, but exclude all member implementations and declarations of private members that have no observable impact on their API contract. For more information, see [Reference assemblies](#).

The **ProduceOnlyReferenceAssembly** and **ProduceReferenceAssembly** options are mutually exclusive.

C# compiler options for security

12/28/2021 • 4 minutes to read • [Edit Online](#)

The following options control compiler security options. The new MSBuild syntax is shown in **Bold**. The older *csc.exe* syntax is shown in `code style`.

- **PublicSign** / `-publicsign` : Publicly sign the assembly.
- **DelaySign** / `-delaysign` : Delay-sign the assembly using only the public portion of the strong name key.
- **KeyFile** / `-keyfile` : Specify a strong name key file.
- **KeyContainer** / `-keycontainer` : Specify a strong name key container.
- **HighEntropyVA** / `-highentropyva` : Enable high-entropy Address Space Layout Randomization (ASLR)

PublicSign

This option causes the compiler to apply a public key but doesn't actually sign the assembly. The **PublicSign** option also sets a bit in the assembly that tells the runtime that the file is signed.

```
<PublicSign>true</PublicSign>
```

The **PublicSign** option requires the use of the [KeyFile](#) or [KeyContainer](#) option. The [keyFile](#) and [KeyContainer](#) options specify the public key. The **PublicSign** and **DelaySign** options are mutually exclusive. Sometimes called "fake sign" or "OSS sign", public signing includes the public key in an output assembly and sets the "signed" flag. Public signing doesn't actually sign the assembly with a private key. Developers use public sign for open-source projects. People build assemblies that are compatible with the released "fully signed" assemblies when they don't have access to the private key used to sign the assemblies. Since few consumers actually need to check if the assembly is fully signed, these publicly built assemblies are useable in almost every scenario where the fully signed one would be used.

DelaySign

This option causes the compiler to reserve space in the output file so that a digital signature can be added later.

```
<DelaySign>true</DelaySign>
```

Use **DelaySign**- if you want a fully signed assembly. Use **DelaySign** if you only want to place the public key in the assembly. The **DelaySign** option has no effect unless used with [KeyFile](#) or [KeyContainer](#). The [KeyContainer](#) and [PublicSign](#) options are mutually exclusive. When you request a fully signed assembly, the compiler hashes the file that contains the manifest (assembly metadata) and signs that hash with the private key. That operation creates a digital signature that is stored in the file that contains the manifest. When an assembly is delay signed, the compiler doesn't compute and store the signature. Instead, the compiler but reserves space in the file so the signature can be added later.

Using **DelaySign** allows a tester to put the assembly in the global cache. After testing, you can fully sign the assembly by placing the private key in the assembly using the [Assembly Linker](#) utility. For more information, see [Creating and Using Strong-Named Assemblies](#) and [Delay Signing an Assembly](#).

KeyFile

Specifies the filename containing the cryptographic key.

```
<KeyFile>filename</KeyFile>
```

`file` is the name of the file containing the strong name key. When this option is used, the compiler inserts the public key from the specified file into the assembly manifest and then signs the final assembly with the private key. To generate a key file, type `sn -k file` at the command line. If you compile with **-target:module**, the name of the key file is held in the module and incorporated into the assembly created when you compile an assembly with **AddModules**. You can also pass your encryption information to the compiler with **KeyContainer**. Use **DelaySign** if you want a partially signed assembly. In case both **KeyFile** and **KeyContainer** are specified in the same compilation, the compiler will first try the key container. If that succeeds, then the assembly is signed with the information in the key container. If the compiler doesn't find the key container, it will try the file specified with **KeyFile**. If that succeeds, the assembly is signed with the information in the key file and the key information will be installed in the key container. On the next compilation, the key container will be valid. A key file might contain only the public key. For more information, see [Creating and Using Strong-Named Assemblies](#) and [Delay Signing an Assembly](#).

KeyContainer

Specifies the name of the cryptographic key container.

```
<KeyContainer>container</KeyContainer>
```

`container` is the name of the strong name key container. When the **KeyContainer** option is used, the compiler creates a sharable component. The compiler inserts a public key from the specified container into the assembly manifest and signs the final assembly with the private key. To generate a key file, type `sn -k file` at the command line. `sn -i` installs the key pair into a container. This option isn't supported when the compiler runs on CoreCLR. To sign an assembly when building on CoreCLR, use the **KeyFile** option. If you compile with **TargetType**, the name of the key file is held in the module and incorporated into the assembly when you compile this module into an assembly with **AddModules**. You can also specify this option as a custom attribute (**System.Reflection.AssemblyKeyNameAttribute**) in the source code for any Microsoft intermediate language (MSIL) module. You can also pass your encryption information to the compiler with **KeyFile**. Use **DelaySign** to add the public key to the assembly manifest but signing the assembly until it has been tested. For more information, see [Creating and Using Strong-Named Assemblies](#) and [Delay Signing an Assembly](#).

HighEntropyVA

The **HighEntropyVA** compiler option tells the Windows kernel whether a particular executable supports high entropy Address Space Layout Randomization (ASLR).

```
<HighEntropyVA>true</HighEntropyVA>
```

This option specifies that a 64-bit executable or an executable that is marked by the **PlatformTarget** compiler option supports a high entropy virtual address space. The option is disabled by default. Use **HighEntropyVA** to enable it.

The **HighEntropyVA** option enables compatible versions of the Windows kernel to use higher degrees of entropy when randomizing the address space layout of a process as part of ASLR. Using higher degrees of entropy means a larger number of addresses can be allocated to memory regions such as stacks and heaps. As a result, it's more difficult to guess the location of a particular memory region. The **HighEntropyVA** compiler option requires the target executable and any modules that it depends on can handle pointer values larger than

4 gigabytes (GB) when they're running as a 64-bit process.

C# Compiler Options that specify resources

12/28/2021 • 5 minutes to read • [Edit Online](#)

The following options control how the C# compiler creates or imports Win32 resources. The new MSBuild syntax is shown in **Bold**. The older *csc.exe* syntax is shown in `code style`.

- **Win32Resource** / `-win32res`: Specify a Win32 resource file (.res).
- **Win32Icon** / `-win32icon`: Reference metadata from the specified assembly file or files.
- **Win32Manifest** / `-win32manifest`: Specify a Win32 manifest file (.xml).
- **NoWin32Manifest** / `-nowin32manifest`: Don't include the default Win32 manifest.
- **Resources** / `-resource`: Embed the specified resource (Short form: /res).
- **LinkResources** / `-linkresources`: Link the specified resource to this assembly.

Win32Resource

The **Win32Resource** option inserts a Win32 resource in the output file.

```
<Win32Resource>filename</Win32Resource>
```

`filename` is the resource file that you want to add to your output file. A Win32 resource can contain version or bitmap (icon) information that would help identify your application in the File Explorer. If you don't specify this option, the compiler will generate version information based on the assembly version.

Win32Icon

The **Win32Icon** option inserts an .ico file in the output file, which gives the output file the desired appearance in the File Explorer.

```
<Win32Icon>filename</Win32Icon>
```

`filename` is the .ico file that you want to add to your output file. An .ico file can be created with the [Resource Compiler](#). The Resource Compiler is invoked when you compile a Visual C++ program; an .ico file is created from the .rc file.

Win32Manifest

Use the **Win32Manifest** option to specify a user-defined Win32 application manifest file to be embedded into a project's portable executable (PE) file.

```
<Win32Manifest>filename</Win32Manifest>
```

`filename` is the name and location of the custom manifest file. By default, the C# compiler embeds an application manifest that specifies a requested execution level of "asInvoker". It creates the manifest in the same folder in which the executable is built. If you want to supply a custom manifest, for example to specify a requested execution level of "highestAvailable" or "requireAdministrator," use this option to specify the name of the file.

NOTE

This option and the **Win32Resources** option are mutually exclusive. If you try to use both options in the same command line you will get a build error.

An application that has no application manifest that specifies a requested execution level will be subject to file and registry virtualization under the User Account Control feature in Windows. For more information, see [User Account Control](#).

Your application will be subject to virtualization if either of these conditions is true:

- You use the **NoWin32Manifest** option and you don't provide a manifest in a later build step or as part of a Windows Resource (.res) file by using the **Win32Resource** option.
- You provide a custom manifest that doesn't specify a requested execution level.

Visual Studio creates a default *.manifest* file and stores it in the debug and release directories alongside the executable file. You can add a custom manifest by creating one in any text editor and then adding the file to the project. Or, you can right-click the **Project** icon in **Solution Explorer**, select **Add New Item**, and then select **Application Manifest File**. After you've added your new or existing manifest file, it will appear in the **Manifest** drop down list. For more information, see [Application Page, Project Designer \(C#\)](#).

You can provide the application manifest as a custom post-build step or as part of a Win32 resource file by using the **NoWin32Manifest** option. Use that same option if you want your application to be subject to file or registry virtualization on Windows Vista.

NoWin32Manifest

Use the **NoWin32Manifest** option to instruct the compiler not to embed any application manifest into the executable file.

```
<NoWin32Manifest />
```

When this option is used, the application will be subject to virtualization on Windows Vista unless you provide an application manifest in a Win32 Resource file or during a later build step.

In Visual Studio, set this option in the **Application Property** page by selecting the **Create Application Without a Manifest** option in the **Manifest** drop down list. For more information, see [Application Page, Project Designer \(C#\)](#).

Resources

Embeds the specified resource into the output file.

```
<Resources Include=filename>  
  <LogicalName>identifier</LogicalName>  
  <Access>accessibility-modifier</Access>  
</Resources>
```

`filename` is the .NET resource file that you want to embed in the output file. `identifier` (optional) is the logical name for the resource; the name that is used to load the resource. The default is the name of the file.

`accessibility-modifier` (optional) is the accessibility of the resource: public or private. The default is public. By default, resources are public in the assembly when they're created by using the C# compiler. To make the resources private, specify `private` as the accessibility modifier. No other accessibility other than `public` or

`private` is allowed. If `filename` is a .NET resource file created, for example, by [Resgen.exe](#) or in the development environment, it can be accessed with members in the [System.Resources](#) namespace. For more information, see [System.Resources.ResourceManager](#). For all other resources, use the `GetManifestResource` methods in the [Assembly](#) class to access the resource at run time. The order of the resources in the output file is determined from the order specified in the project file.

LinkResources

Creates a link to a .NET resource in the output file. The resource file isn't added to the output file.

LinkResources differs from the **Resource** option, which does embed a resource file in the output file.

```
<LinkResources Include=filename>
  <LogicalName>identifier</LogicalName>
  <Access>accessibility-modifier</Access>
</LinkResources>
```

`filename` is the .NET resource file to which you want to link from the assembly. `identifier` (optional) is the logical name for the resource; the name that is used to load the resource. The default is the name of the file. `accessibility-modifier` (optional) is the accessibility of the resource: public or private. The default is public. By default, linked resources are public in the assembly when they're created with the C# compiler. To make the resources private, specify `private` as the accessibility modifier. No other modifier other than `public` or `private` is allowed. If `filename` is a .NET resource file created, for example, by [Resgen.exe](#) or in the development environment, it can be accessed with members in the [System.Resources](#) namespace. For more information, see [System.Resources.ResourceManager](#). For all other resources, use the `GetManifestResource` methods in the [Assembly](#) class to access the resource at run time. The file specified in `filename` can be any format. For example, you may want to make a native DLL part of the assembly, so that it can be installed into the global assembly cache and accessed from managed code in the assembly. You can do the same thing in the Assembly Linker. For more information, see [Al.exe \(Assembly Linker\)](#) and [Working with Assemblies and the Global Assembly Cache](#).

Miscellaneous C# Compiler Options

12/28/2021 • 2 minutes to read • [Edit Online](#)

The following options control miscellaneous compiler behavior. The new MSBuild syntax is shown in **Bold**. The older *csc.exe* syntax is shown in `code style`.

- **ResponseFiles** / `-@`: Read response file for more options.
- **NoLogo** / `-nologo`: Suppress compiler copyright message.
- **NoConfig** / `-noconfig`: Don't auto include *CSC.RSP* file.

ResponseFiles

The **ResponseFiles** option lets you specify a file that contains compiler options and source code files to compile.

```
<ResponseFiles>response_file</ResponseFiles>
```

The `response_file` specifies the file that lists compiler options or source code files to compile. The compiler options and source code files will be processed by the compiler as if they had been specified on the command line. To specify more than one response file in a compilation, specify multiple response file options. In a response file, multiple compiler options and source code files can appear on one line. A single compiler option specification must appear on one line (can't span multiple lines). Response files can have comments that begin with the # symbol. Specifying compiler options from within a response file is just like issuing those commands on the command line. The compiler processes the command options as they're read. Command-line arguments can override previously listed options in response files. Conversely, options in a response file will override options listed previously on the command line or in other response files. C# provides the *csc.rsp* file, which is located in the same directory as the *csc.exe* file. For more information about the response file format, see [NoConfig](#). This compiler option cannot be set in the Visual Studio development environment, nor can it be changed programmatically. The following are a few lines from a sample response file:

```
# build the first output file
-target:exe -out:MyExe.exe source1.cs source2.cs
```

NoLogo

The **NoLogo** option suppresses display of the sign-on banner when the compiler starts up and display of informational messages during compiling.

```
<NoLogo>true</NoLogo>
```

NoConfig

The **NoConfig** option tells the compiler not to compile with the *csc.rsp* file.

```
<NoConfig>true</NoConfig>
```

The *csc.rsp* file references all the assemblies shipped with .NET Framework. The actual references that the Visual

Studio .NET development environment includes depend on the project type. You can modify the *csc.rsp* file and specify additional compiler options that should be included in every compilation. If you don't want the compiler to look for and use the settings in the *csc.rsp* file, specify **NoConfig**. This compiler option is unavailable in Visual Studio and cannot be changed programmatically.

Advanced C# compiler options

12/28/2021 • 10 minutes to read • [Edit Online](#)

The following options support advanced scenarios. The new MSBuild syntax is shown in **Bold**. The older `csc.exe` syntax is shown in `code style`.

- **MainEntryPoint**, **StartupObject** / `-main` : Specify the type that contains the entry point.
- **PdbFile** / `-pdb` : Specify debug information file name.
- **PathMap** / `-pathmap` : Specify a mapping for source path names output by the compiler.
- **ApplicationConfiguration** / `-appconfig` : Specify an application configuration file containing assembly binding settings.
- **AdditionalLibPaths** / `-lib` : Specify additional directories to search in for references.
- **GenerateFullPaths** / `-fullpath` : Compiler generates fully qualified paths.
- **PreferredUILang** / `-preferredUILang` : Specify the preferred output language name.
- **BaseAddress** / `-baseaddress` : Specify the base address for the library to be built.
- **ChecksumAlgorithm** / `-checksumAlgorithm` : Specify algorithm for calculating source file checksum stored in PDB.
- **CodePage** / `-codepage` : Specify the codepage to use when opening source files.
- **Utf8Output** / `-utf8output` : Output compiler messages in UTF-8 encoding.
- **FileAlignment** / `-filealign` : Specify the alignment used for output file sections.
- **ErrorEndLocation** / `-errorEndLocation` : Output line and column of the end location of each error.
- **NoStandardLib** / `-nostdlib` : Don't reference standard library *mscorlib.dll*.
- **SubsystemVersion** / `-subsystemversion` : Specify subsystem version of this assembly.
- **ModuleAssemblyName** / `-moduleAssemblyName` : Name of the assembly that this module will be a part of.

MainEntryPoint or StartupObject

This option specifies the class that contains the entry point to the program, if more than one class contains a `Main` method.

```
<StartupObject>MyNamespace.Program</StartupObject>
```

or

```
<MainEntryPoint>MyNamespace.Program</MainEntryPoint>
```

Where `Program` is the type that contains the `Main` method. The provided class name must be fully qualified; it must include the full namespace containing the class, followed by the class name. For example, when the `Main` method is located inside the `Program` class in the `MyApplication.Core` namespace, the compiler option has to be `-main:MyApplication.Core.Program`. If your compilation includes more than one type with a `Main` method, you can specify which type contains the `Main` method.

NOTE

This option can't be used for a project that includes [top-level statements](#), even if that project contains one or more `Main` methods.

PdbFile

The **PdbFile** compiler option specifies the name and location of the debug symbols file. The `filename` value specifies the name and location of the debug symbols file.

```
<PdbFile>filename</PdbFile>
```

When you specify [DebugType](#), the compiler will create a *.pdb* file in the same directory where the compiler will create the output file (.exe or .dll). The *.pdb* file has the same base file name as the name of the output file.

PdbFile allows you to specify a non-default file name and location for the *.pdb* file. This compiler option cannot be set in the Visual Studio development environment, nor can it be changed programmatically.

PathMap

The **PathMap** compiler option specifies how to map physical paths to source path names output by the compiler. This option maps each physical path on the machine where the compiler runs to a corresponding path that should be written in the output files. In the following example, `path1` is the full path to the source files in the current environment, and `sourcePath1` is the source path substituted for `path1` in any output files. To specify multiple mapped source paths, separate each with a semicolon.

```
<PathMap>path1=sourcePath1;path2=sourcePath2</PathMap>
```

The compiler writes the source path into its output for the following reasons:

1. The source path is substituted for an argument when the [CallerFilePathAttribute](#) is applied to an optional parameter.
2. The source path is embedded in a PDB file.
3. The path of the PDB file is embedded into a PE (portable executable) file.

ApplicationConfiguration

The **ApplicationConfiguration** compiler option enables a C# application to specify the location of an assembly's application configuration (app.config) file to the common language runtime (CLR) at assembly binding time.

```
<ApplicationConfiguration>file</ApplicationConfiguration>
```

Where `file` is the application configuration file that contains assembly binding settings. One use of **ApplicationConfiguration** is advanced scenarios in which an assembly has to reference both the .NET Framework version and the .NET Framework for Silverlight version of a particular reference assembly at the same time. For example, a XAML designer written in Windows Presentation Foundation (WPF) might have to reference both the WPF Desktop, for the designer's user interface, and the subset of WPF that is included with Silverlight. The same designer assembly has to access both assemblies. By default, the separate references cause a compiler error, because assembly binding sees the two assemblies as equivalent. The **ApplicationConfiguration** compiler option enables you to specify the location of an app.config file that

disables the default behavior by using a `<supportPortability>` tag, as shown in the following example.

```
<supportPortability PKT="7cec85d7bea7798e" enable="false"/>
```

The compiler passes the location of the file to the CLR's assembly-binding logic.

NOTE

To use the app.config file that is already set in the project, add property tag `<UseAppConfigForCompiler>` to the .csproj file and set its value to `true`. To specify a different app.config file, add property tag `<AppConfigForCompiler>` and set its value to the location of the file.

The following example shows an app.config file that enables an application to have references to both the .NET Framework implementation and the .NET Framework for Silverlight implementation of any .NET Framework assembly that exists in both implementations. The **ApplicationConfiguration** compiler option specifies the location of this app.config file.

```
<configuration>
  <runtime>
    <assemblyBinding>
      <supportPortability PKT="7cec85d7bea7798e" enable="false"/>
      <supportPortability PKT="31bf3856ad364e35" enable="false"/>
    </assemblyBinding>
  </runtime>
</configuration>
```

AdditionalLibPaths

The **AdditionalLibPaths** option specifies the location of assemblies referenced with the **References** option.

```
<AdditionalLibPaths>dir1[,dir2]</AdditionalLibPaths>
```

Where `dir1` is a directory for the compiler to look in if a referenced assembly isn't found in the current working directory (the directory from which you're invoking the compiler) or in the common language runtime's system directory. `dir2` is one or more additional directories to search in for assembly references. Separate directory names with a comma, and without white space between them. The compiler searches for assembly references that aren't fully qualified in the following order:

1. Current working directory.
2. The common language runtime system directory.
3. Directories specified by **AdditionalLibPaths**.
4. Directories specified by the LIB environment variable.

Use **Reference** to specify an assembly reference. **AdditionalLibPaths** is additive. Specifying it more than once appends to any prior values. Since the path to the dependent assembly isn't specified in the assembly manifest, the application will find and use the assembly in the global assembly cache. The compiler referencing the assembly doesn't imply the common language runtime can find and load the assembly at run time. See [How the Runtime Locates Assemblies](#) for details on how the runtime searches for referenced assemblies.

GenerateFullPaths

The **GenerateFullPaths** option causes the compiler to specify the full path to the file when listing compilation errors and warnings.

```
<GenerateFullPaths>true</GenerateFullPaths>
```

By default, errors and warnings that result from compilation specify the name of the file in which an error was found. The **GenerateFullPaths** option causes the compiler to specify the full path to the file. This compiler option is unavailable in Visual Studio and cannot be changed programmatically.

PreferredUILang

By using the **PreferredUILang** compiler option, you can specify the language in which the C# compiler displays output, such as error messages.

```
<PreferredUILang>language</PreferredUILang>
```

Where `language` is the [language name](#) of the language to use for compiler output. You can use the **PreferredUILang** compiler option to specify the language that you want the C# compiler to use for error messages and other command-line output. If the language pack for the language isn't installed, the language setting of the operating system is used instead.

BaseAddress

The **BaseAddress** option lets you specify the preferred base address at which to load a DLL. For more information about when and why to use this option, see [Larry Osterman's WebLog](#).

```
<BaseAddress>address</BaseAddress>
```

Where `address` is the base address for the DLL. This address can be specified as a decimal, hexadecimal, or octal number. The default base address for a DLL is set by the .NET common language runtime. The lower-order word in this address will be rounded. For example, if you specify `0x11110001`, it will be rounded to `0x11110000`. To complete the signing process for a DLL, use SN.EXE with the -R option.

ChecksumAlgorithm

This option controls the checksum algorithm we use to encode source files in the PDB.

```
<ChecksumAlgorithm>algorithm</ChecksumAlgorithm>
```

The `algorithm` must be either `SHA1` (default) or `SHA256`.

CodePage

This option specifies which codepage to use during compilation if the required page isn't the current default codepage for the system.

```
<CodePage>id</CodePage>
```

Where `id` is the id of the code page to use for all source code files in the compilation. The compiler will first attempt to interpret all source files as UTF-8. If your source code files are in an encoding other than UTF-8 and use characters other than 7-bit ASCII characters, use the **CodePage** option to specify which code page should be used. **CodePage** applies to all source code files in your compilation. See [GetCPIInfo](#) for information on how to find which code pages are supported on your system.

Utf8Output

The **Utf8Output** option displays compiler output using UTF-8 encoding.

```
<Utf8Output>true</Utf8Output>
```

In some international configurations, compiler output cannot correctly be displayed in the console. Use **Utf8Output** and redirect compiler output to a file.

FileAlignment

The **FileAlignment** option lets you specify the size of sections in your output file. Valid values are 512, 1024, 2048, 4096, and 8192. These values are in bytes.

```
<FileAlignment>number</FileAlignment>
```

You set the **FileAlignment** option from the **Advanced** page of the **Build** properties for your project in Visual Studio. Each section will be aligned on a boundary that is a multiple of the **FileAlignment** value. There's no fixed default. If **FileAlignment** isn't specified, the common language runtime picks a default at compile time. By specifying the section size, you affect the size of the output file. Modifying section size may be useful for programs that will run on smaller devices. Use [DUMPBIN](#) to see information about sections in your output file.

ErrorEndLocation

Instructs the compiler to output line and column of the end location of each error.

```
<ErrorEndLocation>true</ErrorEndLocation>
```

By default, the compiler writes the starting location in source for all errors and warnings. When this option is set to true, the compiler writes both the starting and end location for each error and warning.

NoStandardLib

NoStandardLib prevents the import of mscorlib.dll, which defines the entire System namespace.

```
<NoStandardLib>true</NoStandardLib>
```

Use this option if you want to define or create your own System namespace and objects. If you don't specify **NoStandardLib**, mscorlib.dll is imported into your program (same as specifying

```
<NoStandardLib>>false</NoStandardLib> ).
```

SubsystemVersion

Specifies the minimum version of the subsystem on which the executable file runs. Most commonly, this option ensures that the executable file can use security features that aren't available with older versions of Windows.

NOTE

To specify the subsystem itself, use the [TargetType](#) compiler option.

```
<SubsystemVersion>major.minor</SubsystemVersion>
```

The `major.minor` specify the minimum required version of the subsystem, as expressed in a dot notation for major and minor versions. For example, you can specify that an application can't run on an operating system that's older than Windows 7. Set the value of this option to 6.01, as the table later in this article describes. You specify the values for `major` and `minor` as integers. Leading zeroes in the `minor` version don't change the version, but trailing zeroes do. For example, 6.1 and 6.01 refer to the same version, but 6.10 refers to a different version. We recommend expressing the minor version as two digits to avoid confusion.

The following table lists common subsystem versions of Windows.

WINDOWS VERSION	SUBSYSTEM VERSION
Windows Server 2003	5.02
Windows Vista	6.00
Windows 7	6.01
Windows Server 2008	6.01
Windows 8	6.02

The default value of the **SubsystemVersion** compiler option depends on the conditions in the following list:

- The default value is 6.02 if any compiler option in the following list is set:
 - [-target:appcontainerexe](#)
 - [-target:winmdobj](#)
 - [-platform:arm](#)
- The default value is 6.00 if you're using MSBuild, you're targeting .NET Framework 4.5, and you haven't set any of the compiler options that were specified earlier in this list.
- The default value is 4.00 if none of the previous conditions are true.

ModuleAssemblyName

Specifies the name of an assembly whose non-public types a *.netmodule* can access.

```
<ModuleAssemblyName>assembly_name</ModuleAssemblyName>
```

ModuleAssemblyName should be used when building a *.netmodule*, and where the following conditions are true:

- The *.netmodule* needs access to non-public types in an existing assembly.
- You know the name of the assembly into which the *.netmodule* will be built.
- The existing assembly has granted friend assembly access to the assembly into which the *.netmodule* will be built.

For more information on building a *.netmodule*, see [TargetType](#) option of **module**. For more information on friend assemblies, see [Friend Assemblies](#).

XML documentation comments

12/28/2021 • 11 minutes to read • [Edit Online](#)

C# source files can have structured comments that produce API documentation for the types defined in those files. The C# compiler produces an *XML* file that contains structured data representing the comments and the API signatures. Other tools can process that XML output to create human-readable documentation in the form of web pages or PDF files, for example.

This process provides many advantages for you to add API documentation in your code:

- The C# compiler combines the structure of the C# code with the text of the comments into a single XML document.
- The C# compiler verifies that the comments match the API signatures for relevant tags.
- Tools that process the XML documentation files can define XML elements and attributes specific to those tools.

Tools like Visual Studio provide IntelliSense for many common XML elements used in documentation comments.

This article covers these topics:

- Documentation comments and XML file generation
- Tags validated by the C# compiler and Visual Studio
- Format of the generated XML file

Create XML documentation output

You create documentation for your code by writing special comment fields indicated by triple slashes. The comment fields include XML elements that describe the code block that follows the comments. For example:

```
/// <summary>
/// This class performs an important function.
/// </summary>
public class MyClass {}
```

You set either the [GenerateDocumentationFile](#) or [DocumentationFile](#) option, and the compiler will find all comment fields with XML tags in the source code and create an XML documentation file from those comments. When this option is enabled, the compiler generates the [CS1591](#) warning for any publicly visible member declared in your project without XML documentation comments.

XML comment formats

The use of XML doc comments requires delimiters that indicate where a documentation comment begins and ends. You use the following delimiters with the XML documentation tags:

- `///` Single-line delimiter: The documentation examples and C# project templates use this form. If there's white space following the delimiter, it isn't included in the XML output.

NOTE

Visual Studio automatically inserts the `<summary>` and `</summary>` tags and positions your cursor within these tags after you type the `///` delimiter in the code editor. You can turn this feature on or off in the [Options dialog box](#).

- `/** */` Multiline delimiters: The `/** */` delimiters have the following formatting rules:
 - On the line that contains the `/**` delimiter, if the rest of the line is white space, the line isn't processed for comments. If the first character after the `/**` delimiter is white space, that white-space character is ignored and the rest of the line is processed. Otherwise, the entire text of the line after the `/**` delimiter is processed as part of the comment.
 - On the line that contains the `*/` delimiter, if there's only white space up to the `*/` delimiter, that line is ignored. Otherwise, the text on the line up to the `*/` delimiter is processed as part of the comment.
 - For the lines after the one that begins with the `/**` delimiter, the compiler looks for a common pattern at the beginning of each line. The pattern can consist of optional white space and an asterisk (`*`), followed by more optional white space. If the compiler finds a common pattern at the beginning of each line that doesn't begin with the `/**` delimiter or end with the `*/` delimiter, it ignores that pattern for each line.
 - The only part of the following comment that's processed is the line that begins with `<summary>`. The three tag formats produce the same comments.

```
/** <summary>text</summary> */  
  
/**  
<summary>text</summary>  
*/  
  
/**  
* <summary>text</summary>  
*/
```

- The compiler identifies a common pattern of " * " at the beginning of the second and third lines. The pattern isn't included in the output.

```
/**  
* <summary>  
* text </summary>*/
```

- The compiler finds no common pattern in the following comment because the second character on the third line isn't an asterisk. All text on the second and third lines is processed as part of the comment.

```
/**  
* <summary>  
  text </summary>  
*/
```

- The compiler finds no pattern in the following comment for two reasons. First, the number of spaces before the asterisk isn't consistent. Second, the fifth line begins with a tab, which doesn't match spaces. All text from lines two through five is processed as part of the comment.

```
/**
 * <summary>
 * text
 * text2
 * </summary>
 */
```

To refer to XML elements (for example, your function processes specific XML elements that you want to describe in an XML documentation comment), you can use the standard quoting mechanism (`<` and `>`). To refer to generic identifiers in code reference (`cref`) elements, you can use either the escape characters (for example, `cref="List<T>"`) or braces (`cref="List{T}"`). As a special case, the compiler parses the braces as angle brackets to make the documentation comment less cumbersome to author when referring to generic identifiers.

NOTE

The XML documentation comments are not metadata; they are not included in the compiled assembly and therefore they are not accessible through reflection.

Tools that accept XML documentation input

The following tools create output from XML comments:

- **DocFX:** *DocFX* is an API documentation generator for .NET, which currently supports C#, Visual Basic, and F#. It also allows you to customize the generated reference documentation. DocFX builds a static HTML website from your source code and Markdown files. Also, DocFX provides you the flexibility to customize the layout and style of your website through templates. You can also create custom templates.
- **Sandcastle:** The *Sandcastle tools* create help files for managed class libraries containing both conceptual and API reference pages. The Sandcastle tools are command-line based and have no GUI front-end, project management features, or automated build process. The Sandcastle Help File Builder provides standalone GUI and command-line based tools to build a help file in an automated fashion. A Visual Studio integration package is also available for it so that help projects can be created and managed entirely from within Visual Studio.
- **Doxygen:** *Doxygen* generates an on-line documentation browser (in HTML) or an off-line reference manual (in LaTeX) from a set of documented source files. There's also support for generating output in RTF (MS Word), PostScript, hyperlinked PDF, compressed HTML, DocBook, and Unix man pages. You can configure Doxygen to extract the code structure from undocumented source files.

ID strings

Each type or member is stored in an element in the output XML file. Each of those elements has a unique ID string that identifies the type or member. The ID string must account for operators, parameters, return values, generic type parameters, `ref`, `in`, and `out` parameters. To encode all those potential elements, the compiler follows clearly defined rules for generating the ID strings. Programs that process the XML file use the ID string to identify the corresponding .NET metadata or reflection item that the documentation applies to.

The compiler observes the following rules when it generates the ID strings:

- No white space is in the string.
- The first part of the string identifies the kind of member using a single character followed by a colon. The following member types are used:

CHARACTER	MEMBER TYPE	NOTES
N	namespace	You can't add documentation comments to a namespace, but you can make cref references to them, where supported.
T	type	A type is a class, interface, struct, enum, or delegate.
F	field	
P	property	Includes indexers or other indexed properties.
M	method	Includes special methods, such as constructors and operators.
E	event	
!	error string	The rest of the string provides information about the error. The C# compiler generates error information for links that cannot be resolved.

- The second part of the string is the fully qualified name of the item, starting at the root of the namespace. The name of the item, its enclosing type(s), and namespace are separated by periods. If the name of the item itself has periods, they're replaced by the hash-sign ('#'). It's assumed that no item has a hash-sign directly in its name. For example, the fully qualified name of the String constructor is "System.String.#ctor".
- For properties and methods, the parameter list enclosed in parentheses follows. If there are no parameters, no parentheses are present. The parameters are separated by commas. The encoding of each parameter follows directly how it's encoded in a .NET signature (See [Microsoft.VisualStudio.CoreDebugInterop.CorElementType](#) for definitions of the all caps elements in the following list):
 - Base types. Regular types (`ELEMENT_TYPE_CLASS` or `ELEMENT_TYPE_VALUETYPE`) are represented as the fully qualified name of the type.
 - Intrinsic types (for example, `ELEMENT_TYPE_I4`, `ELEMENT_TYPE_OBJECT`, `ELEMENT_TYPE_STRING`, `ELEMENT_TYPE_TYPEDBYREF`, and `ELEMENT_TYPE_VOID`) are represented as the fully qualified name of the corresponding full type. For example, `System.Int32` or `System.TypedReference`.
 - `ELEMENT_TYPE_PTR` is represented as a '*' following the modified type.
 - `ELEMENT_TYPE_BYREF` is represented as a '@' following the modified type.
 - `ELEMENT_TYPE_CMOD_OPT` is represented as a '!' and the fully qualified name of the modifier class, following the modified type.
 - `ELEMENT_TYPE_SZARRAY` is represented as "[]" following the element type of the array.
 - `ELEMENT_TYPE_ARRAY` is represented as [*lowerbound*:*size*,*lowerbound*:*size*] where the number of commas is the rank - 1, and the lower bounds and size of each dimension, if known, are represented in decimal. If a lower bound or size isn't specified, it's omitted. If the lower bound and size for a particular dimension are omitted, the ':' is omitted as well. For example, a two-dimensional array with 1 as the lower bounds and unspecified sizes is [1;1:].
- For conversion operators only (`op_Implicit` and `op_Explicit`), the return value of the method is

encoded as a `~` followed by the return type. For example:

`<member name="M:System.Decimal.op_Explicit(System.Decimal arg)~System.Int32">` is the tag for the cast operator `public static explicit operator int (decimal value);` declared in the `System.Decimal` class.

- For generic types, the name of the type is followed by a backtick and then a number that indicates the number of generic type parameters. For example: `<member name="T:SampleClass`2">` is the tag for a type that is defined as `public class SampleClass<T, U>`. For methods that take generic types as parameters, the generic type parameters are specified as numbers prefaced with backticks (for example ``0`,`1`). Each number represents a zero-based array notation for the type's generic parameters.
 - `ELEMENT_TYPE_PINNED` is represented as a `^` following the modified type. The C# compiler never generates this encoding.
 - `ELEMENT_TYPE_CMOD_REQ` is represented as a `|` and the fully qualified name of the modifier class, following the modified type. The C# compiler never generates this encoding.
 - `ELEMENT_TYPE_GENERICARRAY` is represented as `[?]` following the element type of the array. The C# compiler never generates this encoding.
 - `ELEMENT_TYPE_FNPTR` is represented as `=FUNC: type (signature)`, where `type` is the return type, and `signature` is the arguments of the method. If there are no arguments, the parentheses are omitted. The C# compiler never generates this encoding.
 - The following signature components aren't represented because they aren't used to differentiate overloaded methods:
 - calling convention
 - return type
 - `ELEMENT_TYPE_SENTINEL`

The following examples show how the ID strings for a class and its members are generated:

```
namespace MyNamespace
{
    /// <summary>
    /// Enter description here for class X.
    /// ID string generated is "T:MyNamespace.X".
    /// </summary>
    public unsafe class MyClass
    {
        /// <summary>
        /// Enter description here for the first constructor.
        /// ID string generated is "M:MyNamespace.MyClass.#ctor".
        /// </summary>
        public MyClass() { }

        /// <summary>
        /// Enter description here for the second constructor.
        /// ID string generated is "M:MyNamespace.MyClass.#ctor(System.Int32)".
        /// </summary>
        /// <param name="i">Describe parameter.</param>
        public MyClass(int i) { }

        /// <summary>
        /// Enter description here for field message.
        /// ID string generated is "F:MyNamespace.MyClass.message".
        /// </summary>
        public string message;

        /// <summary>
        /// Enter description for constant PI.
        /// ID string generated is "F:MyNamespace.MyClass.PI".
        /// </summary>
        public const double PI = 3.14;
    }
}
```

```

    /// <summary>
    /// Enter description for method func.
    /// ID string generated is "M:MyNamespace.MyClass.func".
    /// </summary>
    /// <returns>Describe return value.</returns>
    public int func() { return 1; }

    /// <summary>
    /// Enter description for method someMethod.
    /// ID string generated is
    "M:MyNamespace.MyClass.someMethod(System.String,System.Int32@,System.Void*)".
    /// </summary>
    /// <param name="str">Describe parameter.</param>
    /// <param name="num">Describe parameter.</param>
    /// <param name="ptr">Describe parameter.</param>
    /// <returns>Describe return value.</returns>
    public int someMethod(string str, ref int nm, void* ptr) { return 1; }

    /// <summary>
    /// Enter description for method anotherMethod.
    /// ID string generated is
    "M:MyNamespace.MyClass.anotherMethod(System.Int16[],System.Int32[0:,0:])".
    /// </summary>
    /// <param name="array1">Describe parameter.</param>
    /// <param name="array">Describe parameter.</param>
    /// <returns>Describe return value.</returns>
    public int anotherMethod(short[] array1, int[,] array) { return 0; }

    /// <summary>
    /// Enter description for operator.
    /// ID string generated is
    "M:MyNamespace.MyClass.op_Addition(MyNamespace.MyClass,MyNamespace.MyClass)".
    /// </summary>
    /// <param name="first">Describe parameter.</param>
    /// <param name="second">Describe parameter.</param>
    /// <returns>Describe return value.</returns>
    public static MyClass operator +(MyClass first, MyClass second) { return first; }

    /// <summary>
    /// Enter description for property.
    /// ID string generated is "P:MyNamespace.MyClass.prop".
    /// </summary>
    public int prop { get { return 1; } set { } }

    /// <summary>
    /// Enter description for event.
    /// ID string generated is "E:MyNamespace.MyClass.OnHappened".
    /// </summary>
    public event Del OnHappened;

    /// <summary>
    /// Enter description for index.
    /// ID string generated is "P:MyNamespace.MyClass.Item(System.String)".
    /// </summary>
    /// <param name="str">Describe parameter.</param>
    /// <returns></returns>
    public int this[string s] { get { return 1; } }

    /// <summary>
    /// Enter description for class Nested.
    /// ID string generated is "T:MyNamespace.MyClass.Nested".
    /// </summary>
    public class Nested { }

    /// <summary>
    /// Enter description for delegate.
    /// ID string generated is "T:MyNamespace.MyClass.Del".
    /// </summary>
    /// <param name="i">Describe parameter.</param>

```

```

/// <param name="myParameter">Describe parameter.</param>
public delegate void Del(int i);

/// <summary>
/// Enter description for operator.
/// ID string generated is "M:MyNamespace.MyClass.op_Explicit(MyNamespace.X)~System.Int32".
/// </summary>
/// <param name="myParameter">Describe parameter.</param>
/// <returns>Describe return value.</returns>
public static explicit operator int(MyClass myParameter) { return 1; }
}

```

C# language specification

For more information, see the [C# Language Specification](#) annex on documentation comments.

Recommended XML tags for C# documentation comments

12/28/2021 • 12 minutes to read • [Edit Online](#)

C# documentation comments use XML elements to define the structure of the output documentation. One consequence of this feature is that you can add any valid XML in your documentation comments. The C# compiler copies these elements into the output XML file. While you can use any valid XML in your comments (including any valid HTML element), documenting code is recommended for many reasons.

What follows are some recommendations, general use case scenarios, and things that you should know when using XML documentation tags in your C# code. While you can put any tags into your documentation comments, this article describes the recommended tags for the most common language constructs. In all cases, you should adhere to these recommendations:

- For the sake of consistency, all publicly visible types and their public members should be documented.
- Private members can also be documented using XML comments. However, it exposes the inner (potentially confidential) workings of your library.
- At a bare minimum, types and their members should have a `<summary>` tag because its content is needed for IntelliSense.
- Documentation text should be written using complete sentences ending with full stops.
- Partial classes are fully supported, and documentation information will be concatenated into a single entry for each type.

XML documentation starts with `///`. When you create a new project, the templates put some starter `///` lines in for you. The processing of these comments has some restrictions:

- The documentation must be well-formed XML. If the XML isn't well formed, the compiler generates a warning. The documentation file will contain a comment that says that an error was encountered.
- Some of the recommended tags have special meanings:
 - The `<param>` tag is used to describe parameters. If used, the compiler verifies that the parameter exists and that all parameters are described in the documentation. If the verification fails, the compiler issues a warning.
 - The `cref` attribute can be attached to any tag to reference a code element. The compiler verifies that this code element exists. If the verification fails, the compiler issues a warning. The compiler respects any `using` statements when it looks for a type described in the `cref` attribute.
 - The `<summary>` tag is used by IntelliSense inside Visual Studio to display additional information about a type or member.

NOTE

The XML file does not provide full information about the type and members (for example, it does not contain any type information). To get full information about a type or member, use the documentation file together with reflection on the actual type or member.

- Developers are free to create their own set of tags. The compiler will copy these to the output file.

Some of the recommended tags can be used on any language element. Others have more specialized usage. Finally, some of the tags are used to format text in your documentation. This article describes the recommended tags organized by their use.

The compiler verifies the syntax of the elements followed by a single * in the following list. Visual Studio provides IntelliSense for the tags verified by the compiler and all tags followed by ** in the following list. In addition to the tags listed here, the compiler and Visual Studio validate the ``, `<i>`, `<u>`, `
`, and `<a>` tags. The compiler also validates `<tt>`, which is deprecated HTML.

- **General Tags** used for multiple elements - These tags are the minimum set for any API.
 - `<summary>`: The value of this element is displayed in IntelliSense in Visual Studio.
 - `<remarks>` **
- **Tags used for members** - These tags are used when documenting methods and properties.
 - `<returns>`: The value of this element is displayed in IntelliSense in Visual Studio.
 - `<param>` *: The value of this element is displayed in IntelliSense in Visual Studio.
 - `<paramref>`
 - `<exception>` *
 - `<value>`: The value of this element is displayed in IntelliSense in Visual Studio.
- **Format documentation output** - These tags provide formatting directions for tools that generate documentation.
 - `<para>`
 - `<list>`
 - `<c>`
 - `<code>`
 - `<example>` **
- **Reuse documentation text** - These tags provide tools that make it easier to reuse XML comments.
 - `<inheritdoc>` **
 - `<include>` *
- **Generate links and references** - These tags generate links to other documentation.
 - `<see>` *
 - `<seealso>` *
 - `<cref>`
 - `<href>`
- **Tags for generic types and methods** - These tags are used only on generic types and methods
 - `<typeparam>` *: The value of this element is displayed in IntelliSense in Visual Studio.
 - `<typeparamref>`

NOTE

Documentation comments cannot be applied to a namespace.

If you want angle brackets to appear in the text of a documentation comment, use the HTML encoding of `<` and `>`, which is `<` and `>` respectively. This encoding is shown in the following example.

```
/// <summary>
/// This property always returns a value &lt; 1.
/// </summary>
```

General tags

<summary>

```
<summary>description</summary>
```

The `<summary>` tag should be used to describe a type or a type member. Use `<remarks>` to add supplemental information to a type description. Use the [cref attribute](#) to enable documentation tools such as [DocFX](#) and [Sandcastle](#) to create internal hyperlinks to documentation pages for code elements. The text for the `<summary>` tag is the only source of information about the type in IntelliSense, and is also displayed in the Object Browser window.

<remarks>

```
<remarks>  
description  
</remarks>
```

The `<remarks>` tag is used to add information about a type or a type member, supplementing the information specified with `<summary>`. This information is displayed in the Object Browser window. This tag may include more lengthy explanations. You may find that using `<CDATA>` sections for markdown make writing it more convenient. Tools such as [docfx](#) process the markdown text in `<CDATA>` sections.

Document members

<returns>

```
<returns>description</returns>
```

The `<returns>` tag should be used in the comment for a method declaration to describe the return value.

<param>

```
<param name="name">description</param>
```

- `name`: The name of a method parameter. Enclose the name in double quotation marks (" "). The names for parameters must match the API signature. If one or more parameter aren't covered, the compiler issues a warning. The compiler also issues a warning if the value of `name` doesn't match a formal parameter in the method declaration.

The `<param>` tag should be used in the comment for a method declaration to describe one of the parameters for the method. To document multiple parameters, use multiple `<param>` tags. The text for the `<param>` tag is displayed in IntelliSense, the Object Browser, and the Code Comment Web Report.

<paramref>

```
<paramref name="name"/>
```

- `name`: The name of the parameter to refer to. Enclose the name in double quotation marks (" ").

The `<paramref>` tag gives you a way to indicate that a word in the code comments, for example in a `<summary>` or `<remarks>` block refers to a parameter. The XML file can be processed to format this word in some distinct way, such as with a bold or italic font.

<exception>

```
<exception cref="member">description</exception>
```

- `cref = "member"`: A reference to an exception that is available from the current compilation environment. The compiler checks that the given exception exists and translates `member` to the canonical element name in the output XML. `member` must appear within double quotation marks (" ").

The `<exception>` tag lets you specify which exceptions can be thrown. This tag can be applied to definitions for methods, properties, events, and indexers.

<value>

```
<value>property-description</value>
```

The `<value>` tag lets you describe the value that a property represents. When you add a property via code wizard in the Visual Studio .NET development environment, it adds a `<summary>` tag for the new property. You manually add a `<value>` tag to describe the value that the property represents.

Format documentation output

<para>

```
<remarks>
  <para>
    This is an introductory paragraph.
  </para>
  <para>
    This paragraph contains more details.
  </para>
</remarks>
```

The `<para>` tag is for use inside a tag, such as `<summary>`, `<remarks>`, or `<returns>`, and lets you add structure to the text. The `<para>` tag creates a double spaced paragraph. Use the `
` tag if you want a single spaced paragraph.

<list>

```
<list type="bullet|number|table">
  <listheader>
    <term>term</term>
    <description>description</description>
  </listheader>
  <item>
    <term>Assembly</term>
    <description>The library or executable built from a compilation.</description>
  </item>
</list>
```

The `<listheader>` block is used to define the heading row of either a table or definition list. When defining a table, you only need to supply an entry for `term` in the heading. Each item in the list is specified with an `<item>` block. When creating a definition list, you'll need to specify both `term` and `description`. However, for a table, bulleted list, or numbered list, you only need to supply an entry for `description`. A list or table can have as many `<item>` blocks as needed.

<c>

```
<c>text</c>
```

The `<c>` tag gives you a way to indicate that text within a description should be marked as code. Use `<code>` to indicate multiple lines as code.

<code>

```
<code>
    var index = 5;
    index++;
</code>
```

The `<code>` tag is used to indicate multiple lines of code. Use `<c>` to indicate that single-line text within a description should be marked as code.

<example>

```
<example>
This shows how to increment an integer.
<code>
    var index = 5;
    index++;
</code>
</example>
```

The `<example>` tag lets you specify an example of how to use a method or other library member. An example commonly involves using the `<code>` tag.

Reuse documentation text

<inheritdoc>

```
<inheritdoc [cref=""] [path=""]/>
```

Inherit XML comments from base classes, interfaces, and similar methods. Using `inheritdoc` eliminates unwanted copying and pasting of duplicate XML comments and automatically keeps XML comments synchronized. Note that when you add the `<inheritdoc>` tag to a type, all members will inherit the comments as well.

- `cref`: Specify the member to inherit documentation from. Already defined tags on the current member are not overridden by the inherited ones.
- `path`: The XPath expression query that will result in a node set to show. You can use this attribute to filter the tags to include or exclude from the inherited documentation.

Add your XML comments in base classes or interfaces and let `inheritdoc` copy the comments to implementing classes. Add your XML comments to your synchronous methods and let `inheritdoc` copy the comments to your asynchronous versions of the same methods. If you want to copy the comments from a specific member, you use the `cref` attribute to specify the member.

<include>

```
<include file='filename' path='tagpath[@name="id"]' />
```

- `filename`: The name of the XML file containing the documentation. The file name can be qualified with a path

relative to the source code file. Enclose `filename` in single quotation marks (' ').

- `tagpath` : The path of the tags in `filename` that leads to the tag `name` . Enclose the path in single quotation marks (' ').
- `name` : The name specifier in the tag that precedes the comments; `name` will have an `id` .
- `id` : The ID for the tag that precedes the comments. Enclose the ID in double quotation marks (" ").

The `<include>` tag lets you refer to comments in another file that describe the types and members in your source code. Including an external file is an alternative to placing documentation comments directly in your source code file. By putting the documentation in a separate file, you can apply source control to the documentation separately from the source code. One person can have the source code file checked out and someone else can have the documentation file checked out. The `<include>` tag uses the XML XPath syntax. Refer to XPath documentation for ways to customize your `<include>` use.

Generate links and references

`<see>`

```
/// <see cref="member"/>
// or
/// <see cref="member">Link text</see>
// or
/// <see href="link">Link Text</see>
// or
/// <see langword="keyword"/>
```

- `cref="member"` : A reference to a member or field that is available to be called from the current compilation environment. The compiler checks that the given code element exists and passes `member` to the element name in the output XML. Place *member* within double quotation marks (" "). You can provide different link text for a "cref", by using a separate closing tag.
- `href="link"` : A clickable link to a given URL. For example, `<see href="https://github.com">GitHub</see>` produces a clickable link with text GitHub that links to `https://github.com` .
- `langword="keyword"` : A language keyword, such as `true` .

The `<see>` tag lets you specify a link from within text. Use `<seealso>` to indicate that text should be placed in a See Also section. Use the `cref attribute` to create internal hyperlinks to documentation pages for code elements. You include the type parameters to specify a reference to a generic type or method, such as `cref="IDictionary{T, U}"` . Also, `href` is a valid attribute that will function as a hyperlink.

`<seealso>`

```
/// <seealso cref="member"/>
// or
/// <seealso href="link">Link Text</seealso>
```

- `cref="member"` : A reference to a member or field that is available to be called from the current compilation environment. The compiler checks that the given code element exists and passes `member` to the element name in the output XML. `member` must appear within double quotation marks (" ").
- `href="link"` : A clickable link to a given URL. For example, `<seealso href="https://github.com">GitHub</seealso>` produces a clickable link with text GitHub that links to `https://github.com` .

The `<seealso>` tag lets you specify the text that you might want to appear in a **See Also** section. Use `<see>` to specify a link from within text. You cannot nest the `<seealso>` tag inside the `summary` tag.

cref attribute

The `cref` attribute in an XML documentation tag means "code reference." It specifies that the inner text of the tag is a code element, such as a type, method, or property. Documentation tools like [DocFX](#) and [Sandcastle](#) use the `cref` attributes to automatically generate hyperlinks to the page where the type or member is documented.

href attribute

The `href` attribute means a reference to a web page. You can use it to directly reference online documentation about your API or library.

Generic types and methods

<typeparam>

```
<typeparam name="TResult">The type returned from this method</typeparam>
```

- `TResult` : The name of the type parameter. Enclose the name in double quotation marks (" ").

The `<typeparam>` tag should be used in the comment for a generic type or method declaration to describe a type parameter. Add a tag for each type parameter of the generic type or method. The text for the `<typeparam>` tag will be displayed in IntelliSense.

<typeparamref>

```
<typeparamref name="TKey"/>
```

- `TKey` : The name of the type parameter. Enclose the name in double quotation marks (" ").

Use this tag to enable consumers of the documentation file to format the word in some distinct way, for example in italics.

User-defined tags

All the tags outlined above represent those tags that are recognized by the C# compiler. However, a user is free to define their own tags. Tools like Sandcastle bring support for extra tags like `<event>` and `<note>`, and even support [documenting namespaces](#). Custom or in-house documentation generation tools can also be used with the standard tags, and multiple output formats from HTML to PDF can be supported.

Example XML documentation comments

12/28/2021 • 18 minutes to read • [Edit Online](#)

This article contains three examples for adding XML documentation comments to most C# language elements. The first example shows how you document a class with different members. The second shows how you would reuse explanations for a hierarchy of classes or interfaces. The third shows tags to use for generic classes and members. The second and third examples use concepts that are covered in the first example.

Document a class, struct, or interface

The following example shows common language elements, and the tags you'll likely use to describe these elements. The documentation comments describe the use of the tags, rather than the class itself.

```
/// <summary>
/// Every class and member should have a one sentence
/// summary describing its purpose.
/// </summary>
/// <remarks>
/// You can expand on that one sentence summary to
/// provide more information for readers. In this case,
/// the <c>ExampleClass</c> provides different C#
/// elements to show how you would add documentation
/// comments for most elements in a typical class.
/// <para>
/// The remarks can add multiple paragraphs, so you can
/// write detailed information for developers that use
/// your work. You should add everything needed for
/// readers to be successful. This class contains
/// examples for the following:
/// </para>
/// <list type="table">
/// <item>
/// <term>Summary</term>
/// <description>
/// This should provide a one sentence summary of the class or member.
/// </description>
/// </item>
/// <item>
/// <term>Remarks</term>
/// <description>
/// This is typically a more detailed description of the class or member
/// </description>
/// </item>
/// <item>
/// <term>para</term>
/// <description>
/// The para tag separates a section into multiple paragraphs
/// </description>
/// </item>
/// <item>
/// <term>list</term>
/// <description>
/// Provides a list of terms or elements
/// </description>
/// </item>
/// <item>
/// <term>returns, param</term>
/// <description>
/// Used to describe parameters and return values
/// </description>
```

```

/// </item>
/// <item>
/// <term>value</term>
/// <description>Used to describe properties</description>
/// </item>
/// <item>
/// <term>exception</term>
/// <description>
/// Used to describe exceptions that may be thrown
/// </description>
/// </item>
/// <item>
/// <term>c, cref, see, seealso</term>
/// <description>
/// These provide code style and links to other
/// documentation elements
/// </description>
/// </item>
/// <item>
/// <term>example, code</term>
/// <description>
/// These are used for code examples
/// </description>
/// </item>
/// </list>
/// <para>
/// The list above uses the "table" style. You could
/// also use the "bullet" or "number" style. Neither
/// would typically use the "term" element.
/// <br/>
/// Note: paragraphs are double spaced. Use the *br*
/// tag for single spaced lines.
/// </para>
/// </remarks>
public class ExampleClass
{
    /// <value>
    /// The <c>Label</c> property represents a label
    /// for this instance.
    /// </value>
    /// <remarks>
    /// The <see cref="Label"/> is a <see langword="string"/>
    /// that you use for a label.
    /// <para>
    /// Note that there isn't a way to provide a "cref" to
    /// each accessor, only to the property itself.
    /// </para>
    /// </remarks>
    public string Label
    {
        get;
        set;
    }

    /// <summary>
    /// Adds two integers and returns the result.
    /// </summary>
    /// <returns>
    /// The sum of two integers.
    /// </returns>
    /// <param name="left">
    /// The left operand of the addition.
    /// </param>
    /// <param name="right">
    /// The right operand of the addition.
    /// </param>
    /// <example>
    /// <code>
    /// int c = Math.Add(4, 5);

```

```

    /// if (c > 10)
    /// {
    ///     Console.WriteLine(c);
    /// }
    /// </code>
    /// </example>
    /// <exception cref="System.OverflowException">
    /// Thrown when one parameter is
    /// <see cref="Int32.MaxValue">MaxValue</see> and the other is
    /// greater than 0.
    /// Note that here you can also use
    /// <see href="https://docs.microsoft.com/dotnet/api/system.int32.maxvalue"/>
    /// to point a web page instead.
    /// </exception>
    /// <see cref="ExampleClass"/> for a list of all
    /// the tags in these examples.
    /// <seealso cref="ExampleClass.Label"/>
    public static int Add(int left, int right)
    {
        if ((left == int.MaxValue && right > 0) || (right == int.MaxValue && left > 0))
            throw new System.OverflowException();

        return left + right;
    }
}

    /// <summary>
    /// This is an example of a positional record.
    /// </summary>
    /// <remarks>
    /// There isn't a way to add XML comments for properties
    /// created for positional records, yet. The language
    /// design team is still considering what tags should
    /// be supported, and where. Currently, you can use
    /// the "param" tag to describe the parameters to the
    /// primary constructor.
    /// </remarks>
    /// <param name="FirstName">
    /// This tag will apply to the primary constructor parameter.
    /// </param>
    /// <param name="LastName">
    /// This tag will apply to the primary constructor parameter.
    /// </param>
    public record Person(string FirstName, string LastName);
}

```

Adding documentation can clutter your source code with large sets of comments intended for users of your library. You use the `<Include>` tag to separate your XML comments from your source. Your source code references an XML file with the `<Include>` tag:

```

    /// <include file='xml_include_tag.xml' path='MyDocs/MyMembers[@name="test"]/*' />
    class Test
    {
        static void Main()
        {
        }
    }

    /// <include file='xml_include_tag.xml' path='MyDocs/MyMembers[@name="test2"]/*' />
    class Test2
    {
        public void Test()
        {
        }
    }
}

```

The second file, *xml_include_tag.xml*, contains the documentation comments.

```
<MyDocs>
  <MyMembers name="test">
    <summary>
      The summary for this type.
    </summary>
  </MyMembers>
  <MyMembers name="test2">
    <summary>
      The summary for this other type.
    </summary>
  </MyMembers>
</MyDocs>
```

Document a hierarchy of classes and interfaces

The `<inheritdoc>` element means a type or member *inherits* documentation comments from a base class or interface. You can also use the `<inheritdoc>` element with the `cref` attribute to inherit comments from a member of the same type. The following example shows ways to use this tag. Note that when you add the `inheritdoc` attribute to a type, member comments are inherited. You can prevent the use of inherited comments by writing comments on the members in the derived type. Those will be chosen over the inherited comments.

```
/// <summary>
/// A summary about this class.
/// </summary>
/// <remarks>
/// These remarks would explain more about this class.
/// In this example, these comments also explain the
/// general information about the derived class.
/// </remarks>
public class MainClass
{
}

///<inheritdoc/>
public class DerivedClass : MainClass
{
}

/// <summary>
/// This interface would describe all the methods in
/// its contract.
/// </summary>
/// <remarks>
/// While elided for brevity, each method or property
/// in this interface would contain docs that you want
/// to duplicate in each implementing class.
/// </remarks>
public interface ITestInterface
{
  /// <summary>
  /// This method is part of the test interface.
  /// </summary>
  /// <remarks>
  /// This content would be inherited by classes
  /// that implement this interface when the
  /// implementing class uses "inheritdoc"
  /// </remarks>
  /// <returns>The value of <paramref name="arg" /> </returns>
  /// <param name="arg">The argument to the method</param>
  int Method(int arg);
}
```

```

}

///
public class ImplementingClass : ITestInterface
{
    // doc comments are inherited here.
    public int Method(int arg) => arg;
}

/// <summary>
/// This class shows hows you can "inherit" the doc
/// comments from one method in another method.
/// </summary>
/// <remarks>
/// You can inherit all comments, or only a specific tag,
/// represented by an xpath expression.
/// </remarks>
public class InheritOnlyReturns
{
    /// <summary>
    /// In this example, this summary is only visible for this method.
    /// </summary>
    /// <returns>A boolean</returns>
    public static bool MyParentMethod(bool x) { return x; }

    /// <inheritdoc cref="MyParentMethod" path="/returns"/>
    public static bool MyChildMethod() { return false; }
}

/// <Summary>
/// This class shows an example ofsharing comments across methods.
/// </Summary>
public class InheritAllButRemarks
{
    /// <summary>
    /// In this example, this summary is visible on all the methods.
    /// </summary>
    /// <remarks>
    /// The remarks can be inherited by other methods
    /// using the xpath expression.
    /// </remarks>
    /// <returns>A boolean</returns>
    public static bool MyParentMethod(bool x) { return x; }

    /// <inheritdoc cref="MyParentMethod" path="//*[not(self::remarks)]"/>
    public static bool MyChildMethod() { return false; }
}

```

Generic types

Use the `<typeparam>` tag to describe type parameters on generic types and methods. The value for the `cref` attribute requires new syntax to reference a generic method or class:

```

/// <summary>
/// This is a generic class.
/// </summary>
/// <remarks>
/// This example shows how to specify the <see cref="GenericClass{T}"/>
/// type as a cref attribute.
/// In generic classes and methods, you'll often want to reference the
/// generic type, or the type parameter.
/// </remarks>
class GenericClass<T>
{
    // Fields and members.
}

/// <Summary>
/// This shows examples of typeparamref and typeparam tags
/// </Summary>
public class ParamsAndParamRefs
{
    /// <summary>
    /// The GetGenericValue method.
    /// </summary>
    /// <remarks>
    /// This sample shows how to specify the <see cref="GetGenericValue"/>
    /// method as a cref attribute.
    /// The parameter and return value are both of an arbitrary type,
    /// <typeparamref name="T"/>
    /// </remarks>
    public static T GetGenericValue<T>(T para)
    {
        return para;
    }
}

```

Math class example

The following code shows a realistic example of adding doc comments to a math library.

```

namespace TaggedLibrary
{
    /*
        The main Math class
        Contains all methods for performing basic math functions
    */
    /// <summary>
    /// The main <c>Math</c> class.
    /// Contains all methods for performing basic math functions.
    /// <list type="bullet">
    /// <item>
    /// <term>Add</term>
    /// <description>Addition Operation</description>
    /// </item>
    /// <item>
    /// <term>Subtract</term>
    /// <description>Subtraction Operation</description>
    /// </item>
    /// <item>
    /// <term>Multiply</term>
    /// <description>Multiplication Operation</description>
    /// </item>
    /// <item>
    /// <term>Divide</term>
    /// <description>Division Operation</description>
    /// </item>
    /// </list>

```

```

/// </summary>
/// <remarks>
/// <para>
/// This class can add, subtract, multiply and divide.
/// </para>
/// <para>
/// These operations can be performed on both
/// integers and doubles.
/// </para>
/// </remarks>
public class Math
{
    // Adds two integers and returns the result
    /// <summary>
    /// Adds two integers <paramref name="a"/> and <paramref name="b"/>
    /// and returns the result.
    /// </summary>
    /// <returns>
    /// The sum of two integers.
    /// </returns>
    /// <example>
    /// <code>
    /// int c = Math.Add(4, 5);
    /// if (c > 10)
    /// {
    ///     Console.WriteLine(c);
    /// }
    /// </code>
    /// </example>
    /// <exception cref="System.OverflowException">
    /// Thrown when one parameter is <see cref="Int32.MaxValue"/> and the other
    /// is greater than 0.
    /// </exception>
    /// See <see cref="Math.Add(double, double)"/> to add doubles.
    /// <seealso cref="Math.Subtract(int, int)"/>
    /// <seealso cref="Math.Multiply(int, int)"/>
    /// <seealso cref="Math.Divide(int, int)"/>
    /// <param name="a">An integer.</param>
    /// <param name="b">An integer.</param>
    public static int Add(int a, int b)
    {
        // If any parameter is equal to the max value of an integer
        // and the other is greater than zero
        if ((a == int.MaxValue && b > 0) ||
            (b == int.MaxValue && a > 0))
        {
            throw new System.OverflowException();
        }
        return a + b;
    }

    // Adds two doubles and returns the result
    /// <summary>
    /// Adds two doubles <paramref name="a"/> and <paramref name="b"/>
    /// and returns the result.
    /// </summary>
    /// <returns>
    /// The sum of two doubles.
    /// </returns>
    /// <example>
    /// <code>
    /// double c = Math.Add(4.5, 5.4);
    /// if (c > 10)
    /// {
    ///     Console.WriteLine(c);
    /// }
    /// </code>
    /// </example>
    /// <exception cref="System.OverflowException">

```

```

/// Thrown when one parameter is max and the other
/// is greater than 0.</exception>
/// See <see cref="Math.Add(int, int)"/> to add integers.
/// <seealso cref="Math.Subtract(double, double)"/>

In the above XML, each member's documentation comments appear directly inside a tag named after what they do. You can choose your own strategy. The code uses the `<include>` tag to reference the appropriate element in the XML file:

```

namespace IncludeTag
{
    /*
        The main Math class
        Contains all methods for performing basic math functions
    */
    /// <include file='include.xml' path='docs/members[@name="math"]/Math/'/>
    public class Math
    {
        // Adds two integers and returns the result
        /// <include file='include.xml' path='docs/members[@name="math"]/AddInt/'/>
        public static int Add(int a, int b)
        {
            // If any parameter is equal to the max value of an integer
            // and the other is greater than zero
            if ((a == int.MaxValue && b > 0) || (b == int.MaxValue && a > 0))
                throw new System.OverflowException();

            return a + b;
        }

        // Adds two doubles and returns the result
        /// <include file='include.xml' path='docs/members[@name="math"]/AddDouble/'/>
        public static double Add(double a, double b)
        {
            // If any parameter is equal to the max value of an integer
            // and the other is greater than zero
            if ((a == double.MaxValue && b > 0) || (b == double.MaxValue && a > 0))
                throw new System.OverflowException();

            return a + b;
        }

        // Subtracts an integer from another and returns the result
        /// <include file='include.xml' path='docs/members[@name="math"]/SubtractInt/'/>
        public static int Subtract(int a, int b)
        {
            return a - b;
        }

        // Subtracts a double from another and returns the result
        /// <include file='include.xml' path='docs/members[@name="math"]/SubtractDouble/'/>
        public static double Subtract(double a, double b)
        {
            return a - b;
        }

        // Multiplies two integers and returns the result
        /// <include file='include.xml' path='docs/members[@name="math"]/MultiplyInt/'/>
        public static int Multiply(int a, int b)
        {
            return a * b;
        }

        // Multiplies two doubles and returns the result
    }
}

```

```

    /// <include file='include.xml' path='docs/members[@name="math"]/MultiplyDouble/*' />
    public static double Multiply(double a, double b)
    {
        return a * b;
    }

    // Divides an integer by another and returns the result
    /// <include file='include.xml' path='docs/members[@name="math"]/DivideInt/*' />
    public static int Divide(int a, int b)
    {
        return a / b;
    }

    // Divides a double by another and returns the result
    /// <include file='include.xml' path='docs/members[@name="math"]/DivideDouble/*' />
    public static double Divide(double a, double b)
    {
        return a / b;
    }
}

```

- The `path` attribute represents an [XPath](#) query to the `tag name` present in the specified `file`.
- The `name` attribute represents the name specifier in the tag that precedes the comments.
- The `id` attribute, which can be used in place of `name`, represents the ID for the tag that precedes the comments.

C# Compiler Errors

12/28/2021 • 2 minutes to read • [Edit Online](#)

Some C# compiler errors have corresponding topics that explain why the error is generated, and, in some cases, how to fix the error. Use one of the following steps to see whether help is available for a particular error message.

- If you're using Visual Studio, choose the error number (for example, CS0029) in the [Output Window](#), and then choose the F1 key.
- Type the error number in the *Filter by title* box in the table of contents.

If none of these steps leads to information about your error, go to the end of this page, and send feedback that includes the number or text of the error.

For information about how to configure error and warning options in C#, see [C# compiler options](#) or the Visual Studio [Build Page, Project Designer \(C#\)](#).

NOTE

Your computer might show different names or locations for some of the Visual Studio user interface elements in the following instructions. The Visual Studio edition that you have and the settings that you use determine these elements. For more information, see [Personalizing the IDE](#).

Introduction

12/28/2021 • 55 minutes to read • [Edit Online](#)

C# (pronounced "See Sharp") is a simple, modern, object-oriented, and type-safe programming language. C# has its roots in the C family of languages and will be immediately familiar to C, C++, and Java programmers. C# is standardized by ECMA International as the *ECMA-334* standard and by ISO/IEC as the *ISO/IEC 23270* standard. Microsoft's C# compiler for the .NET Framework is a conforming implementation of both of these standards.

C# is an object-oriented language, but C# further includes support for *component-oriented* programming. Contemporary software design increasingly relies on software components in the form of self-contained and self-describing packages of functionality. Key to such components is that they present a programming model with properties, methods, and events; they have attributes that provide declarative information about the component; and they incorporate their own documentation. C# provides language constructs to directly support these concepts, making C# a very natural language in which to create and use software components.

Several C# features aid in the construction of robust and durable applications: *Garbage collection* automatically reclaims memory occupied by unused objects; *exception handling* provides a structured and extensible approach to error detection and recovery; and the *type-safe* design of the language makes it impossible to read from uninitialized variables, to index arrays beyond their bounds, or to perform unchecked type casts.

C# has a *unified type system*. All C# types, including primitive types such as `int` and `double`, inherit from a single root `object` type. Thus, all types share a set of common operations, and values of any type can be stored, transported, and operated upon in a consistent manner. Furthermore, C# supports both user-defined reference types and value types, allowing dynamic allocation of objects as well as in-line storage of lightweight structures.

To ensure that C# programs and libraries can evolve over time in a compatible manner, much emphasis has been placed on *versioning* in C#'s design. Many programming languages pay little attention to this issue, and, as a result, programs written in those languages break more often than necessary when newer versions of dependent libraries are introduced. Aspects of C#'s design that were directly influenced by versioning considerations include the separate `virtual` and `override` modifiers, the rules for method overload resolution, and support for explicit interface member declarations.

The rest of this chapter describes the essential features of the C# language. Although later chapters describe rules and exceptions in a detail-oriented and sometimes mathematical manner, this chapter strives for clarity and brevity at the expense of completeness. The intent is to provide the reader with an introduction to the language that will facilitate the writing of early programs and the reading of later chapters.

Hello world

The "Hello, World" program is traditionally used to introduce a programming language. Here it is in C#:

```
using System;

class Hello
{
    static void Main() {
        Console.WriteLine("Hello, World");
    }
}
```

C# source files typically have the file extension `.cs`. Assuming that the "Hello, World" program is stored in the file `hello.cs`, the program can be compiled with the Microsoft C# compiler using the command line

```
csc hello.cs
```

which produces an executable assembly named `hello.exe`. The output produced by this application when it is run is

```
Hello, World
```

The "Hello, World" program starts with a `using` directive that references the `System` namespace. Namespaces provide a hierarchical means of organizing C# programs and libraries. Namespaces contain types and other namespaces—for example, the `System` namespace contains a number of types, such as the `Console` class referenced in the program, and a number of other namespaces, such as `IO` and `Collections`. A `using` directive that references a given namespace enables unqualified use of the types that are members of that namespace. Because of the `using` directive, the program can use `Console.WriteLine` as shorthand for `System.Console.WriteLine`.

The `Hello` class declared by the "Hello, World" program has a single member, the method named `Main`. The `Main` method is declared with the `static` modifier. While instance methods can reference a particular enclosing object instance using the keyword `this`, static methods operate without reference to a particular object. By convention, a static method named `Main` serves as the entry point of a program.

The output of the program is produced by the `WriteLine` method of the `Console` class in the `System` namespace. This class is provided by the .NET Framework class libraries, which, by default, are automatically referenced by the Microsoft C# compiler. Note that C# itself does not have a separate runtime library. Instead, the .NET Framework is the runtime library of C#.

Program structure

The key organizational concepts in C# are *programs*, *namespaces*, *types*, *members*, and *assemblies*. C# programs consist of one or more source files. Programs declare types, which contain members and can be organized into namespaces. Classes and interfaces are examples of types. Fields, methods, properties, and events are examples of members. When C# programs are compiled, they are physically packaged into assemblies. Assemblies typically have the file extension `.exe` or `.dll`, depending on whether they implement *applications* or *libraries*.

The example

```

using System;

namespace Acme.Collections
{
    public class Stack
    {
        Entry top;

        public void Push(object data) {
            top = new Entry(top, data);
        }

        public object Pop() {
            if (top == null) throw new InvalidOperationException();
            object result = top.data;
            top = top.next;
            return result;
        }

        class Entry
        {
            public Entry next;
            public object data;

            public Entry(Entry next, object data) {
                this.next = next;
                this.data = data;
            }
        }
    }
}

```

declares a class named `Stack` in a namespace called `Acme.Collections`. The fully qualified name of this class is `Acme.Collections.Stack`. The class contains several members: a field named `top`, two methods named `Push` and `Pop`, and a nested class named `Entry`. The `Entry` class further contains three members: a field named `next`, a field named `data`, and a constructor. Assuming that the source code of the example is stored in the file `acme.cs`, the command line

```
csc /t:library acme.cs
```

compiles the example as a library (code without a `Main` entry point) and produces an assembly named `acme.dll`.

Assemblies contain executable code in the form of *Intermediate Language* (IL) instructions, and symbolic information in the form of *metadata*. Before it is executed, the IL code in an assembly is automatically converted to processor-specific code by the Just-In-Time (JIT) compiler of .NET Common Language Runtime.

Because an assembly is a self-describing unit of functionality containing both code and metadata, there is no need for `#include` directives and header files in C#. The public types and members contained in a particular assembly are made available in a C# program simply by referencing that assembly when compiling the program. For example, this program uses the `Acme.Collections.Stack` class from the `acme.dll` assembly:

```

using System;
using Acme.Collections;

class Test
{
    static void Main() {
        Stack s = new Stack();
        s.Push(1);
        s.Push(10);
        s.Push(100);
        Console.WriteLine(s.Pop());
        Console.WriteLine(s.Pop());
        Console.WriteLine(s.Pop());
    }
}

```

If the program is stored in the file `test.cs`, when `test.cs` is compiled, the `acme.dll` assembly can be referenced using the compiler's `/r` option:

```
csc /r:acme.dll test.cs
```

This creates an executable assembly named `test.exe`, which, when run, produces the output:

```

100
10
1

```

C# permits the source text of a program to be stored in several source files. When a multi-file C# program is compiled, all of the source files are processed together, and the source files can freely reference each other—conceptually, it is as if all the source files were concatenated into one large file before being processed. Forward declarations are never needed in C# because, with very few exceptions, declaration order is insignificant. C# does not limit a source file to declaring only one public type nor does it require the name of the source file to match a type declared in the source file.

Types and variables

There are two kinds of types in C#: *value types* and *reference types*. Variables of value types directly contain their data whereas variables of reference types store references to their data, the latter being known as objects. With reference types, it is possible for two variables to reference the same object and thus possible for operations on one variable to affect the object referenced by the other variable. With value types, the variables each have their own copy of the data, and it is not possible for operations on one to affect the other (except in the case of `ref` and `out` parameter variables).

C#'s value types are further divided into *simple types*, *enum types*, *struct types*, and *nullable types*, and C#'s reference types are further divided into *class types*, *interface types*, *array types*, and *delegate types*.

The following table provides an overview of C#'s type system.

CATEGORY	TYPES	DESCRIPTION
Value types	Simple types	Signed integral: <code>sbyte</code> , <code>short</code> , <code>int</code> , <code>long</code>
		Unsigned integral: <code>byte</code> , <code>ushort</code> , <code>uint</code> , <code>ulong</code>

CATEGORY	TYPES	DESCRIPTION
		Unicode characters: <code>char</code>
		IEEE floating point: <code>float</code> , <code>double</code>
		High-precision decimal: <code>decimal</code>
		Boolean: <code>bool</code>
	Enum types	User-defined types of the form <code>enum E {...}</code>
	Struct types	User-defined types of the form <code>struct S {...}</code>
	Nullable types	Extensions of all other value types with a <code>null</code> value
Reference types	Class types	Ultimate base class of all other types: <code>object</code>
		Unicode strings: <code>string</code>
		User-defined types of the form <code>class C {...}</code>
	Interface types	User-defined types of the form <code>interface I {...}</code>
	Array types	Single- and multi-dimensional, for example, <code>int[]</code> and <code>int[,]</code>
	Delegate types	User-defined types of the form e.g. <code>delegate int D(...)</code>

The eight integral types provide support for 8-bit, 16-bit, 32-bit, and 64-bit values in signed or unsigned form.

The two floating point types, `float` and `double`, are represented using the 32-bit single-precision and 64-bit double-precision IEEE 754 formats.

The `decimal` type is a 128-bit data type suitable for financial and monetary calculations.

C#'s `bool` type is used to represent boolean values—values that are either `true` or `false`.

Character and string processing in C# uses Unicode encoding. The `char` type represents a UTF-16 code unit, and the `string` type represents a sequence of UTF-16 code units.

The following table summarizes C#'s numeric types.

CATEGORY	BITS	TYPE	RANGE/PRECISION
Signed integral	8	<code>sbyte</code>	-128...127

CATEGORY	BITS	TYPE	RANGE/PRECISION
	16	short	-32,768...32,767
	32	int	-2,147,483,648...2,147,483,647
	64	long	-9,223,372,036,854,775,808...9,223,372,036,854,775,807
Unsigned integral	8	byte	0...255
	16	ushort	0...65,535
	32	uint	0...4,294,967,295
	64	ulong	0...18,446,744,073,709,551,615
Floating point	32	float	1.5×10^{-45} to 3.4×10^{38} , 7-digit precision
	64	double	5.0×10^{-324} to 1.7×10^{308} , 15-digit precision
Decimal	128	decimal	1.0×10^{-28} to 7.9×10^{28} , 28-digit precision

C# programs use ***type declarations*** to create new types. A type declaration specifies the name and the members of the new type. Five of C#'s categories of types are user-definable: class types, struct types, interface types, enum types, and delegate types.

A class type defines a data structure that contains data members (fields) and function members (methods, properties, and others). Class types support single inheritance and polymorphism, mechanisms whereby derived classes can extend and specialize base classes.

A struct type is similar to a class type in that it represents a structure with data members and function members. However, unlike classes, structs are value types and do not require heap allocation. Struct types do not support user-specified inheritance, and all struct types implicitly inherit from type `object`.

An interface type defines a contract as a named set of public function members. A class or struct that implements an interface must provide implementations of the interface's function members. An interface may inherit from multiple base interfaces, and a class or struct may implement multiple interfaces.

A delegate type represents references to methods with a particular parameter list and return type. Delegates make it possible to treat methods as entities that can be assigned to variables and passed as parameters. Delegates are similar to the concept of function pointers found in some other languages, but unlike function pointers, delegates are object-oriented and type-safe.

Class, struct, interface and delegate types all support generics, whereby they can be parameterized with other

types.

An enum type is a distinct type with named constants. Every enum type has an underlying type, which must be one of the eight integral types. The set of values of an enum type is the same as the set of values of the underlying type.

C# supports single- and multi-dimensional arrays of any type. Unlike the types listed above, array types do not have to be declared before they can be used. Instead, array types are constructed by following a type name with square brackets. For example, `int[]` is a single-dimensional array of `int`, `int[,]` is a two-dimensional array of `int`, and `int[][]` is a single-dimensional array of single-dimensional arrays of `int`.

Nullable types also do not have to be declared before they can be used. For each non-nullable value type `T` there is a corresponding nullable type `T?`, which can hold an additional value `null`. For instance, `int?` is a type that can hold any 32 bit integer or the value `null`.

C#'s type system is unified such that a value of any type can be treated as an object. Every type in C# directly or indirectly derives from the `object` class type, and `object` is the ultimate base class of all types. Values of reference types are treated as objects simply by viewing the values as type `object`. Values of value types are treated as objects by performing **boxing** and **unboxing** operations. In the following example, an `int` value is converted to `object` and back again to `int`.

```
using System;

class Test
{
    static void Main() {
        int i = 123;
        object o = i;           // Boxing
        int j = (int)o;         // Unboxing
    }
}
```

When a value of a value type is converted to type `object`, an object instance, also called a "box," is allocated to hold the value, and the value is copied into that box. Conversely, when an `object` reference is cast to a value type, a check is made that the referenced object is a box of the correct value type, and, if the check succeeds, the value in the box is copied out.

C#'s unified type system effectively means that value types can become objects "on demand." Because of the unification, general-purpose libraries that use type `object` can be used with both reference types and value types.

There are several kinds of **variables** in C#, including fields, array elements, local variables, and parameters. Variables represent storage locations, and every variable has a type that determines what values can be stored in the variable, as shown by the following table.

TYPE OF VARIABLE	POSSIBLE CONTENTS
Non-nullable value type	A value of that exact type
Nullable value type	A null value or a value of that exact type
<code>object</code>	A null reference, a reference to an object of any reference type, or a reference to a boxed value of any value type

TYPE OF VARIABLE	POSSIBLE CONTENTS
Class type	A null reference, a reference to an instance of that class type, or a reference to an instance of a class derived from that class type
Interface type	A null reference, a reference to an instance of a class type that implements that interface type, or a reference to a boxed value of a value type that implements that interface type
Array type	A null reference, a reference to an instance of that array type, or a reference to an instance of a compatible array type
Delegate type	A null reference or a reference to an instance of that delegate type

Expressions

Expressions are constructed from **operands** and **operators**. The operators of an expression indicate which operations to apply to the operands. Examples of operators include `+`, `-`, `*`, `/`, and `new`. Examples of operands include literals, fields, local variables, and expressions.

When an expression contains multiple operators, the **precedence** of the operators controls the order in which the individual operators are evaluated. For example, the expression `x + y * z` is evaluated as `x + (y * z)` because the `*` operator has higher precedence than the `+` operator.

Most operators can be **overloaded**. Operator overloading permits user-defined operator implementations to be specified for operations where one or both of the operands are of a user-defined class or struct type.

The following table summarizes C#'s operators, listing the operator categories in order of precedence from highest to lowest. Operators in the same category have equal precedence.

CATEGORY	EXPRESSION	DESCRIPTION
Primary	<code>x.m</code>	Member access
	<code>x(...)</code>	Method and delegate invocation
	<code>x[...]</code>	Array and indexer access
	<code>x++</code>	Post-increment
	<code>x--</code>	Post-decrement
	<code>new T(...)</code>	Object and delegate creation
	<code>new T(...){...}</code>	Object creation with initializer
	<code>new {...}</code>	Anonymous object initializer
	<code>new T[...]</code>	Array creation

CATEGORY	EXPRESSION	DESCRIPTION
	<code>typeof(T)</code>	Obtain <code>System.Type</code> object for <code>T</code>
	<code>checked(x)</code>	Evaluate expression in checked context
	<code>unchecked(x)</code>	Evaluate expression in unchecked context
	<code>default(T)</code>	Obtain default value of type <code>T</code>
	<code>delegate {...}</code>	Anonymous function (anonymous method)
Unary	<code>+x</code>	Identity
	<code>-x</code>	Negation
	<code>!x</code>	Logical negation
	<code>~x</code>	Bitwise negation
	<code>++x</code>	Pre-increment
	<code>--x</code>	Pre-decrement
	<code>(T)x</code>	Explicitly convert <code>x</code> to type <code>T</code>
	<code>await x</code>	Asynchronously wait for <code>x</code> to complete
Multiplicative	<code>x * y</code>	Multiplication
	<code>x / y</code>	Division
	<code>x % y</code>	Remainder
Additive	<code>x + y</code>	Addition, string concatenation, delegate combination
	<code>x - y</code>	Subtraction, delegate removal
Shift	<code>x << y</code>	Shift left
	<code>x >> y</code>	Shift right
Relational and type testing	<code>x < y</code>	Less than
	<code>x > y</code>	Greater than
	<code>x <= y</code>	Less than or equal

CATEGORY	EXPRESSION	DESCRIPTION
	<code>x >= y</code>	Greater than or equal
	<code>x is T</code>	Return <code>true</code> if <code>x</code> is a <code>T</code> , <code>false</code> otherwise
	<code>x as T</code>	Return <code>x</code> typed as <code>T</code> , or <code>null</code> if <code>x</code> is not a <code>T</code>
Equality	<code>x == y</code>	Equal
	<code>x != y</code>	Not equal
Logical AND	<code>x & y</code>	Integer bitwise AND, boolean logical AND
Logical XOR	<code>x ^ y</code>	Integer bitwise XOR, boolean logical XOR
Logical OR	<code>x y</code>	Integer bitwise OR, boolean logical OR
Conditional AND	<code>x && y</code>	Evaluates <code>y</code> only if <code>x</code> is <code>true</code>
Conditional OR	<code>x y</code>	Evaluates <code>y</code> only if <code>x</code> is <code>false</code>
Null coalescing	<code>x ?? y</code>	Evaluates to <code>y</code> if <code>x</code> is <code>null</code> , to <code>x</code> otherwise
Conditional	<code>x ? y : z</code>	Evaluates <code>y</code> if <code>x</code> is <code>true</code> , <code>z</code> if <code>x</code> is <code>false</code>
Assignment or anonymous function	<code>x = y</code>	Assignment
	<code>x op= y</code>	Compound assignment; supported operators are <code>*=</code> , <code>/=</code> , <code>%=</code> , <code>+=</code> , <code>-=</code> , <code><<=</code> , <code>>>=</code> , <code>&=</code> , <code>^=</code> , <code> =</code>
	<code>(T x) => y</code>	Anonymous function (lambda expression)

Statements

The actions of a program are expressed using **statements**. C# supports several different kinds of statements, a number of which are defined in terms of embedded statements.

A **block** permits multiple statements to be written in contexts where a single statement is allowed. A block consists of a list of statements written between the delimiters `{` and `}`.

Declaration statements are used to declare local variables and constants.

Expression statements are used to evaluate expressions. Expressions that can be used as statements include method invocations, object allocations using the `new` operator, assignments using `=` and the compound assignment operators, increment and decrement operations using the `++` and `--` operators and `await`

expressions.

Selection statements are used to select one of a number of possible statements for execution based on the value of some expression. In this group are the `if` and `switch` statements.

Iteration statements are used to repeatedly execute an embedded statement. In this group are the `while`, `do`, `for`, and `foreach` statements.

Jump statements are used to transfer control. In this group are the `break`, `continue`, `goto`, `throw`, `return`, and `yield` statements.

The `try ... catch` statement is used to catch exceptions that occur during execution of a block, and the `try ... finally` statement is used to specify finalization code that is always executed, whether an exception occurred or not.

The `checked` and `unchecked` statements are used to control the overflow checking context for integral-type arithmetic operations and conversions.

The `lock` statement is used to obtain the mutual-exclusion lock for a given object, execute a statement, and then release the lock.

The `using` statement is used to obtain a resource, execute a statement, and then dispose of that resource.

Below are examples of each kind of statement

Local variable declarations

```
static void Main() {  
    int a;  
    int b = 2, c = 3;  
    a = 1;  
    Console.WriteLine(a + b + c);  
}
```

Local constant declaration

```
static void Main() {  
    const float pi = 3.1415927f;  
    const int r = 25;  
    Console.WriteLine(pi * r * r);  
}
```

Expression statement

```
static void Main() {  
    int i;  
    i = 123;           // Expression statement  
    Console.WriteLine(i); // Expression statement  
    i++;              // Expression statement  
    Console.WriteLine(i); // Expression statement  
}
```

`if` statement

```
static void Main(string[] args) {
    if (args.Length == 0) {
        Console.WriteLine("No arguments");
    }
    else {
        Console.WriteLine("One or more arguments");
    }
}
```

switch statement

```
static void Main(string[] args) {
    int n = args.Length;
    switch (n) {
        case 0:
            Console.WriteLine("No arguments");
            break;
        case 1:
            Console.WriteLine("One argument");
            break;
        default:
            Console.WriteLine("{0} arguments", n);
            break;
    }
}
```

while statement

```
static void Main(string[] args) {
    int i = 0;
    while (i < args.Length) {
        Console.WriteLine(args[i]);
        i++;
    }
}
```

do statement

```
static void Main() {
    string s;
    do {
        s = Console.ReadLine();
        if (s != null) Console.WriteLine(s);
    } while (s != null);
}
```

for statement

```
static void Main(string[] args) {
    for (int i = 0; i < args.Length; i++) {
        Console.WriteLine(args[i]);
    }
}
```

foreach statement

```
static void Main(string[] args) {  
    foreach (string s in args) {  
        Console.WriteLine(s);  
    }  
}
```

break statement

```
static void Main() {  
    while (true) {  
        string s = Console.ReadLine();  
        if (s == null) break;  
        Console.WriteLine(s);  
    }  
}
```

continue statement

```
static void Main(string[] args) {  
    for (int i = 0; i < args.Length; i++) {  
        if (args[i].StartsWith("/")) continue;  
        Console.WriteLine(args[i]);  
    }  
}
```

goto statement

```
static void Main(string[] args) {  
    int i = 0;  
    goto check;  
loop:  
    Console.WriteLine(args[i++]);  
check:  
    if (i < args.Length) goto loop;  
}
```

return statement

```
static int Add(int a, int b) {  
    return a + b;  
}  
  
static void Main() {  
    Console.WriteLine(Add(1, 2));  
    return;  
}
```

yield statement

```

static IEnumerable<int> Range(int from, int to) {
    for (int i = from; i < to; i++) {
        yield return i;
    }
    yield break;
}

static void Main() {
    foreach (int x in Range(-10,10)) {
        Console.WriteLine(x);
    }
}

```

throw and **try** statements

```

static double Divide(double x, double y) {
    if (y == 0) throw new DivideByZeroException();
    return x / y;
}

static void Main(string[] args) {
    try {
        if (args.Length != 2) {
            throw new Exception("Two numbers required");
        }
        double x = double.Parse(args[0]);
        double y = double.Parse(args[1]);
        Console.WriteLine(Divide(x, y));
    }
    catch (Exception e) {
        Console.WriteLine(e.Message);
    }
    finally {
        Console.WriteLine("Good bye!");
    }
}

```

checked and **unchecked** statements

```

static void Main() {
    int i = int.MaxValue;
    checked {
        Console.WriteLine(i + 1);    // Exception
    }
    unchecked {
        Console.WriteLine(i + 1);    // Overflow
    }
}

```

lock statement

```

class Account
{
    decimal balance;
    public void Withdraw(decimal amount) {
        lock (this) {
            if (amount > balance) {
                throw new Exception("Insufficient funds");
            }
            balance -= amount;
        }
    }
}

```

using **statement**

```

static void Main() {
    using (TextWriter w = File.CreateText("test.txt")) {
        w.WriteLine("Line one");
        w.WriteLine("Line two");
        w.WriteLine("Line three");
    }
}

```

Classes and objects

Classes are the most fundamental of C#'s types. A class is a data structure that combines state (fields) and actions (methods and other function members) in a single unit. A class provides a definition for dynamically created *instances* of the class, also known as *objects*. Classes support *inheritance* and *polymorphism*, mechanisms whereby *derived classes* can extend and specialize *base classes*.

New classes are created using class declarations. A class declaration starts with a header that specifies the attributes and modifiers of the class, the name of the class, the base class (if given), and the interfaces implemented by the class. The header is followed by the class body, which consists of a list of member declarations written between the delimiters `{` and `}`.

The following is a declaration of a simple class named `Point`:

```

public class Point
{
    public int x, y;

    public Point(int x, int y) {
        this.x = x;
        this.y = y;
    }
}

```

Instances of classes are created using the `new` operator, which allocates memory for a new instance, invokes a constructor to initialize the instance, and returns a reference to the instance. The following statements create two `Point` objects and store references to those objects in two variables:

```

Point p1 = new Point(0, 0);
Point p2 = new Point(10, 20);

```

The memory occupied by an object is automatically reclaimed when the object is no longer in use. It is neither necessary nor possible to explicitly deallocate objects in C#.

Members

The members of a class are either *static members* or *instance members*. Static members belong to classes, and instance members belong to objects (instances of classes).

The following table provides an overview of the kinds of members a class can contain.

MEMBER	DESCRIPTION
Constants	Constant values associated with the class
Fields	Variables of the class
Methods	Computations and actions that can be performed by the class
Properties	Actions associated with reading and writing named properties of the class
Indexers	Actions associated with indexing instances of the class like an array
Events	Notifications that can be generated by the class
Operators	Conversions and expression operators supported by the class
Constructors	Actions required to initialize instances of the class or the class itself
Destructors	Actions to perform before instances of the class are permanently discarded
Types	Nested types declared by the class

Accessibility

Each member of a class has an associated accessibility, which controls the regions of program text that are able to access the member. There are five possible forms of accessibility. These are summarized in the following table.

ACCESSIBILITY	MEANING
<code>public</code>	Access not limited
<code>protected</code>	Access limited to this class or classes derived from this class
<code>internal</code>	Access limited to this program
<code>protected internal</code>	Access limited to this program or classes derived from this class
<code>private</code>	Access limited to this class

Type parameters

A class definition may specify a set of type parameters by following the class name with angle brackets enclosing a list of type parameter names. The type parameters can then be used in the body of the class

declarations to define the members of the class. In the following example, the type parameters of `Pair` are `TFirst` and `TSecond` :

```
public class Pair<TFirst,TSecond>
{
    public TFirst First;
    public TSecond Second;
}
```

A class type that is declared to take type parameters is called a generic class type. Struct, interface and delegate types can also be generic.

When the generic class is used, type arguments must be provided for each of the type parameters:

```
Pair<int,string> pair = new Pair<int,string> { First = 1, Second = "two" };
int i = pair.First;    // TFirst is int
string s = pair.Second; // TSecond is string
```

A generic type with type arguments provided, like `Pair<int,string>` above, is called a constructed type.

Base classes

A class declaration may specify a base class by following the class name and type parameters with a colon and the name of the base class. Omitting a base class specification is the same as deriving from type `object` . In the following example, the base class of `Point3D` is `Point` , and the base class of `Point` is `object` :

```
public class Point
{
    public int x, y;

    public Point(int x, int y) {
        this.x = x;
        this.y = y;
    }
}

public class Point3D: Point
{
    public int z;

    public Point3D(int x, int y, int z): base(x, y) {
        this.z = z;
    }
}
```

A class inherits the members of its base class. Inheritance means that a class implicitly contains all members of its base class, except for the instance and static constructors, and the destructors of the base class. A derived class can add new members to those it inherits, but it cannot remove the definition of an inherited member. In the previous example, `Point3D` inherits the `x` and `y` fields from `Point` , and every `Point3D` instance contains three fields, `x` , `y` , and `z` .

An implicit conversion exists from a class type to any of its base class types. Therefore, a variable of a class type can reference an instance of that class or an instance of any derived class. For example, given the previous class declarations, a variable of type `Point` can reference either a `Point` or a `Point3D` :

```
Point a = new Point(10, 20);
Point b = new Point3D(10, 20, 30);
```

Fields

A field is a variable that is associated with a class or with an instance of a class.

A field declared with the `static` modifier defines a **static field**. A static field identifies exactly one storage location. No matter how many instances of a class are created, there is only ever one copy of a static field.

A field declared without the `static` modifier defines an **instance field**. Every instance of a class contains a separate copy of all the instance fields of that class.

In the following example, each instance of the `Color` class has a separate copy of the `r`, `g`, and `b` instance fields, but there is only one copy of the `Black`, `White`, `Red`, `Green`, and `Blue` static fields:

```
public class Color
{
    public static readonly Color Black = new Color(0, 0, 0);
    public static readonly Color White = new Color(255, 255, 255);
    public static readonly Color Red = new Color(255, 0, 0);
    public static readonly Color Green = new Color(0, 255, 0);
    public static readonly Color Blue = new Color(0, 0, 255);
    private byte r, g, b;

    public Color(byte r, byte g, byte b) {
        this.r = r;
        this.g = g;
        this.b = b;
    }
}
```

As shown in the previous example, **read-only fields** may be declared with a `readonly` modifier. Assignment to a `readonly` field can only occur as part of the field's declaration or in a constructor in the same class.

Methods

A **method** is a member that implements a computation or action that can be performed by an object or class.

Static methods are accessed through the class. **Instance methods** are accessed through instances of the class.

Methods have a (possibly empty) list of **parameters**, which represent values or variable references passed to the method, and a **return type**, which specifies the type of the value computed and returned by the method. A method's return type is `void` if it does not return a value.

Like types, methods may also have a set of type parameters, for which type arguments must be specified when the method is called. Unlike types, the type arguments can often be inferred from the arguments of a method call and need not be explicitly given.

The **signature** of a method must be unique in the class in which the method is declared. The signature of a method consists of the name of the method, the number of type parameters and the number, modifiers, and types of its parameters. The signature of a method does not include the return type.

Parameters

Parameters are used to pass values or variable references to methods. The parameters of a method get their actual values from the **arguments** that are specified when the method is invoked. There are four kinds of parameters: value parameters, reference parameters, output parameters, and parameter arrays.

A **value parameter** is used for input parameter passing. A value parameter corresponds to a local variable that gets its initial value from the argument that was passed for the parameter. Modifications to a value parameter do not affect the argument that was passed for the parameter.

Value parameters can be optional, by specifying a default value so that corresponding arguments can be omitted.

A **reference parameter** is used for both input and output parameter passing. The argument passed for a reference parameter must be a variable, and during execution of the method, the reference parameter represents the same storage location as the argument variable. A reference parameter is declared with the `ref` modifier. The following example shows the use of `ref` parameters.

```
using System;

class Test
{
    static void Swap(ref int x, ref int y) {
        int temp = x;
        x = y;
        y = temp;
    }

    static void Main() {
        int i = 1, j = 2;
        Swap(ref i, ref j);
        Console.WriteLine("{0} {1}", i, j);           // Outputs "2 1"
    }
}
```

An **output parameter** is used for output parameter passing. An output parameter is similar to a reference parameter except that the initial value of the caller-provided argument is unimportant. An output parameter is declared with the `out` modifier. The following example shows the use of `out` parameters.

```
using System;

class Test
{
    static void Divide(int x, int y, out int result, out int remainder) {
        result = x / y;
        remainder = x % y;
    }

    static void Main() {
        int res, rem;
        Divide(10, 3, out res, out rem);
        Console.WriteLine("{0} {1}", res, rem);      // Outputs "3 1"
    }
}
```

A **parameter array** permits a variable number of arguments to be passed to a method. A parameter array is declared with the `params` modifier. Only the last parameter of a method can be a parameter array, and the type of a parameter array must be a single-dimensional array type. The `Write` and `WriteLine` methods of the `System.Console` class are good examples of parameter array usage. They are declared as follows.

```
public class Console
{
    public static void Write(string fmt, params object[] args) {...}
    public static void WriteLine(string fmt, params object[] args) {...}
    ...
}
```

Within a method that uses a parameter array, the parameter array behaves exactly like a regular parameter of an array type. However, in an invocation of a method with a parameter array, it is possible to pass either a single argument of the parameter array type or any number of arguments of the element type of the parameter array. In the latter case, an array instance is automatically created and initialized with the given arguments. This example

```
Console.WriteLine("x={0} y={1} z={2}", x, y, z);
```

is equivalent to writing the following.

```
string s = "x={0} y={1} z={2}";
object[] args = new object[3];
args[0] = x;
args[1] = y;
args[2] = z;
Console.WriteLine(s, args);
```

Method body and local variables

A method's body specifies the statements to execute when the method is invoked.

A method body can declare variables that are specific to the invocation of the method. Such variables are called **local variables**. A local variable declaration specifies a type name, a variable name, and possibly an initial value. The following example declares a local variable `i` with an initial value of zero and a local variable `j` with no initial value.

```
using System;

class Squares
{
    static void Main() {
        int i = 0;
        int j;
        while (i < 10) {
            j = i * i;
            Console.WriteLine("{0} x {0} = {1}", i, j);
            i = i + 1;
        }
    }
}
```

C# requires a local variable to be **definitely assigned** before its value can be obtained. For example, if the declaration of the previous `i` did not include an initial value, the compiler would report an error for the subsequent usages of `i` because `i` would not be definitely assigned at those points in the program.

A method can use `return` statements to return control to its caller. In a method returning `void`, `return` statements cannot specify an expression. In a method returning non-`void`, `return` statements must include an expression that computes the return value.

Static and instance methods

A method declared with a `static` modifier is a **static method**. A static method does not operate on a specific instance and can only directly access static members.

A method declared without a `static` modifier is an **instance method**. An instance method operates on a specific instance and can access both static and instance members. The instance on which an instance method was invoked can be explicitly accessed as `this`. It is an error to refer to `this` in a static method.

The following `Entity` class has both static and instance members.

```

class Entity
{
    static int nextSerialNo;
    int serialNo;

    public Entity() {
        serialNo = nextSerialNo++;
    }

    public int GetSerialNo() {
        return serialNo;
    }

    public static int GetNextSerialNo() {
        return nextSerialNo;
    }

    public static void SetNextSerialNo(int value) {
        nextSerialNo = value;
    }
}

```

Each `Entity` instance contains a serial number (and presumably some other information that is not shown here). The `Entity` constructor (which is like an instance method) initializes the new instance with the next available serial number. Because the constructor is an instance member, it is permitted to access both the `serialNo` instance field and the `nextSerialNo` static field.

The `GetNextSerialNo` and `SetNextSerialNo` static methods can access the `nextSerialNo` static field, but it would be an error for them to directly access the `serialNo` instance field.

The following example shows the use of the `Entity` class.

```

using System;

class Test
{
    static void Main() {
        Entity.SetNextSerialNo(1000);
        Entity e1 = new Entity();
        Entity e2 = new Entity();
        Console.WriteLine(e1.GetSerialNo());           // Outputs "1000"
        Console.WriteLine(e2.GetSerialNo());           // Outputs "1001"
        Console.WriteLine(Entity.GetNextSerialNo());   // Outputs "1002"
    }
}

```

Note that the `SetNextSerialNo` and `GetNextSerialNo` static methods are invoked on the class whereas the `GetSerialNo` instance method is invoked on instances of the class.

Virtual, override, and abstract methods

When an instance method declaration includes a `virtual` modifier, the method is said to be a *virtual method*. When no `virtual` modifier is present, the method is said to be a *non-virtual method*.

When a virtual method is invoked, the *run-time type* of the instance for which that invocation takes place determines the actual method implementation to invoke. In a nonvirtual method invocation, the *compile-time type* of the instance is the determining factor.

A virtual method can be *overridden* in a derived class. When an instance method declaration includes an `override` modifier, the method overrides an inherited virtual method with the same signature. Whereas a virtual method declaration introduces a new method, an override method declaration specializes an existing

inherited virtual method by providing a new implementation of that method.

An ***abstract*** method is a virtual method with no implementation. An abstract method is declared with the `abstract` modifier and is permitted only in a class that is also declared `abstract`. An abstract method must be overridden in every non-abstract derived class.

The following example declares an abstract class, `Expression`, which represents an expression tree node, and three derived classes, `Constant`, `VariableReference`, and `Operation`, which implement expression tree nodes for constants, variable references, and arithmetic operations. (This is similar to, but not to be confused with the expression tree types introduced in [Expression tree types](#)).

```

using System;
using System.Collections;

public abstract class Expression
{
    public abstract double Evaluate(Hashtable vars);
}

public class Constant: Expression
{
    double value;

    public Constant(double value) {
        this.value = value;
    }

    public override double Evaluate(Hashtable vars) {
        return value;
    }
}

public class VariableReference: Expression
{
    string name;

    public VariableReference(string name) {
        this.name = name;
    }

    public override double Evaluate(Hashtable vars) {
        object value = vars[name];
        if (value == null) {
            throw new Exception("Unknown variable: " + name);
        }
        return Convert.ToDouble(value);
    }
}

public class Operation: Expression
{
    Expression left;
    char op;
    Expression right;

    public Operation(Expression left, char op, Expression right) {
        this.left = left;
        this.op = op;
        this.right = right;
    }

    public override double Evaluate(Hashtable vars) {
        double x = left.Evaluate(vars);
        double y = right.Evaluate(vars);
        switch (op) {
            case '+': return x + y;
            case '-': return x - y;
            case '*': return x * y;
            case '/': return x / y;
        }
        throw new Exception("Unknown operator");
    }
}

```

The previous four classes can be used to model arithmetic expressions. For example, using instances of these classes, the expression `x + 3` can be represented as follows.

```
Expression e = new Operation(
    new VariableReference("x"),
    '+',
    new Constant(3));
```

The `Evaluate` method of an `Expression` instance is invoked to evaluate the given expression and produce a `double` value. The method takes as an argument a `Hashtable` that contains variable names (as keys of the entries) and values (as values of the entries). The `Evaluate` method is a virtual abstract method, meaning that non-abstract derived classes must override it to provide an actual implementation.

A `Constant`'s implementation of `Evaluate` simply returns the stored constant. A `VariableReference`'s implementation looks up the variable name in the hashtable and returns the resulting value. An `Operation`'s implementation first evaluates the left and right operands (by recursively invoking their `Evaluate` methods) and then performs the given arithmetic operation.

The following program uses the `Expression` classes to evaluate the expression `x * (y + 2)` for different values of `x` and `y`.

```
using System;
using System.Collections;

class Test
{
    static void Main() {
        Expression e = new Operation(
            new VariableReference("x"),
            '*',
            new Operation(
                new VariableReference("y"),
                '+',
                new Constant(2)
            )
        );
        Hashtable vars = new Hashtable();
        vars["x"] = 3;
        vars["y"] = 5;
        Console.WriteLine(e.Evaluate(vars));           // Outputs "21"
        vars["x"] = 1.5;
        vars["y"] = 9;
        Console.WriteLine(e.Evaluate(vars));           // Outputs "16.5"
    }
}
```

Method overloading

Method **overloading** permits multiple methods in the same class to have the same name as long as they have unique signatures. When compiling an invocation of an overloaded method, the compiler uses **overload resolution** to determine the specific method to invoke. Overload resolution finds the one method that best matches the arguments or reports an error if no single best match can be found. The following example shows overload resolution in effect. The comment for each invocation in the `Main` method shows which method is actually invoked.

```

class Test
{
    static void F() {
        Console.WriteLine("F()");
    }

    static void F(object x) {
        Console.WriteLine("F(object)");
    }

    static void F(int x) {
        Console.WriteLine("F(int)");
    }

    static void F(double x) {
        Console.WriteLine("F(double)");
    }

    static void F<T>(T x) {
        Console.WriteLine("F<T>(T)");
    }

    static void F(double x, double y) {
        Console.WriteLine("F(double, double)");
    }

    static void Main() {
        F();           // Invokes F()
        F(1);          // Invokes F(int)
        F(1.0);        // Invokes F(double)
        F("abc");      // Invokes F(object)
        F((double)1);   // Invokes F(double)
        F((object)1);   // Invokes F(object)
        F<int>(1);      // Invokes F<T>(T)
        F(1, 1);       // Invokes F(double, double)
    }
}

```

As shown by the example, a particular method can always be selected by explicitly casting the arguments to the exact parameter types and/or explicitly supplying type arguments.

Other function members

Members that contain executable code are collectively known as the *function members* of a class. The preceding section describes methods, which are the primary kind of function members. This section describes the other kinds of function members supported by C#: constructors, properties, indexers, events, operators, and destructors.

The following code shows a generic class called `List<T>`, which implements a growable list of objects. The class contains several examples of the most common kinds of function members.

```

public class List<T> {
    // Constant...
    const int defaultCapacity = 4;

    // Fields...
    T[] items;
    int count;

    // Constructors...
    public List(int capacity = defaultCapacity) {
        items = new T[capacity];
    }

    // Properties...

```

```

// ...
public int Count {
    get { return count; }
}
public int Capacity {
    get {
        return items.Length;
    }
    set {
        if (value < count) value = count;
        if (value != items.Length) {
            T[] newItems = new T[value];
            Array.Copy(items, 0, newItems, 0, count);
            items = newItems;
        }
    }
}

// Indexer...
public T this[int index] {
    get {
        return items[index];
    }
    set {
        items[index] = value;
        OnChanged();
    }
}

// Methods...
public void Add(T item) {
    if (count == Capacity) Capacity = count * 2;
    items[count] = item;
    count++;
    OnChanged();
}
protected virtual void OnChanged() {
    if (Changed != null) Changed(this, EventArgs.Empty);
}
public override bool Equals(object other) {
    return Equals(this, other as List<T>);
}
static bool Equals(List<T> a, List<T> b) {
    if (a == null) return b == null;
    if (b == null || a.count != b.count) return false;
    for (int i = 0; i < a.count; i++) {
        if (!object.Equals(a.items[i], b.items[i])) {
            return false;
        }
    }
    return true;
}

// Event...
public event EventHandler Changed;

// Operators...
public static bool operator ==(List<T> a, List<T> b) {
    return Equals(a, b);
}
public static bool operator !=(List<T> a, List<T> b) {
    return !Equals(a, b);
}
}

```

Constructors

C# supports both instance and static constructors. An *instance constructor* is a member that implements the actions required to initialize an instance of a class. A *static constructor* is a member that implements the

actions required to initialize a class itself when it is first loaded.

A constructor is declared like a method with no return type and the same name as the containing class. If a constructor declaration includes a `static` modifier, it declares a static constructor. Otherwise, it declares an instance constructor.

Instance constructors can be overloaded. For example, the `List<T>` class declares two instance constructors, one with no parameters and one that takes an `int` parameter. Instance constructors are invoked using the `new` operator. The following statements allocate two `List<string>` instances using each of the constructors of the `List` class.

```
List<string> list1 = new List<string>();  
List<string> list2 = new List<string>(10);
```

Unlike other members, instance constructors are not inherited, and a class has no instance constructors other than those actually declared in the class. If no instance constructor is supplied for a class, then an empty one with no parameters is automatically provided.

Properties

Properties are a natural extension of fields. Both are named members with associated types, and the syntax for accessing fields and properties is the same. However, unlike fields, properties do not denote storage locations. Instead, properties have **accessors** that specify the statements to be executed when their values are read or written.

A property is declared like a field, except that the declaration ends with a `get` accessor and/or a `set` accessor written between the delimiters `{` and `}` instead of ending in a semicolon. A property that has both a `get` accessor and a `set` accessor is a **read-write property**, a property that has only a `get` accessor is a **read-only property**, and a property that has only a `set` accessor is a **write-only property**.

A `get` accessor corresponds to a parameterless method with a return value of the property type. Except as the target of an assignment, when a property is referenced in an expression, the `get` accessor of the property is invoked to compute the value of the property.

A `set` accessor corresponds to a method with a single parameter named `value` and no return type. When a property is referenced as the target of an assignment or as the operand of `++` or `--`, the `set` accessor is invoked with an argument that provides the new value.

The `List<T>` class declares two properties, `Count` and `Capacity`, which are read-only and read-write, respectively. The following is an example of use of these properties.

```
List<string> names = new List<string>();  
names.Capacity = 100;           // Invokes set accessor  
int i = names.Count;           // Invokes get accessor  
int j = names.Capacity;        // Invokes get accessor
```

Similar to fields and methods, C# supports both instance properties and static properties. Static properties are declared with the `static` modifier, and instance properties are declared without it.

The accessor(s) of a property can be virtual. When a property declaration includes a `virtual`, `abstract`, or `override` modifier, it applies to the accessor(s) of the property.

Indexers

An **indexer** is a member that enables objects to be indexed in the same way as an array. An indexer is declared like a property except that the name of the member is `this` followed by a parameter list written between the delimiters `[` and `]`. The parameters are available in the accessor(s) of the indexer. Similar to properties, indexers can be read-write, read-only, and write-only, and the accessor(s) of an indexer can be virtual.

The `List` class declares a single read-write indexer that takes an `int` parameter. The indexer makes it possible to index `List` instances with `int` values. For example

```
List<string> names = new List<string>();
names.Add("Liz");
names.Add("Martha");
names.Add("Beth");
for (int i = 0; i < names.Count; i++) {
    string s = names[i];
    names[i] = s.ToUpper();
}
```

Indexers can be overloaded, meaning that a class can declare multiple indexers as long as the number or types of their parameters differ.

Events

An **event** is a member that enables a class or object to provide notifications. An event is declared like a field except that the declaration includes an `event` keyword and the type must be a delegate type.

Within a class that declares an event member, the event behaves just like a field of a delegate type (provided the event is not abstract and does not declare accessors). The field stores a reference to a delegate that represents the event handlers that have been added to the event. If no event handles are present, the field is `null`.

The `List<T>` class declares a single event member called `Changed`, which indicates that a new item has been added to the list. The `Changed` event is raised by the `OnChanged` virtual method, which first checks whether the event is `null` (meaning that no handlers are present). The notion of raising an event is precisely equivalent to invoking the delegate represented by the event—thus, there are no special language constructs for raising events.

Clients react to events through **event handlers**. Event handlers are attached using the `+=` operator and removed using the `-=` operator. The following example attaches an event handler to the `Changed` event of a `List<string>`.

```
using System;

class Test
{
    static int changeCount;

    static void ListChanged(object sender, EventArgs e) {
        changeCount++;
    }

    static void Main() {
        List<string> names = new List<string>();
        names.Changed += new EventHandler(ListChanged);
        names.Add("Liz");
        names.Add("Martha");
        names.Add("Beth");
        Console.WriteLine(changeCount);           // Outputs "3"
    }
}
```

For advanced scenarios where control of the underlying storage of an event is desired, an event declaration can explicitly provide `add` and `remove` accessors, which are somewhat similar to the `set` accessor of a property.

Operators

An **operator** is a member that defines the meaning of applying a particular expression operator to instances of a class. Three kinds of operators can be defined: unary operators, binary operators, and conversion operators.

All operators must be declared as `public` and `static`.

The `List<T>` class declares two operators, `operator==` and `operator!=`, and thus gives new meaning to expressions that apply those operators to `List` instances. Specifically, the operators define equality of two `List<T>` instances as comparing each of the contained objects using their `Equals` methods. The following example uses the `==` operator to compare two `List<int>` instances.

```
using System;

class Test
{
    static void Main() {
        List<int> a = new List<int>();
        a.Add(1);
        a.Add(2);
        List<int> b = new List<int>();
        b.Add(1);
        b.Add(2);
        Console.WriteLine(a == b);      // Outputs "True"
        b.Add(3);
        Console.WriteLine(a == b);      // Outputs "False"
    }
}
```

The first `Console.WriteLine` outputs `True` because the two lists contain the same number of objects with the same values in the same order. Had `List<T>` not defined `operator==`, the first `Console.WriteLine` would have output `False` because `a` and `b` reference different `List<int>` instances.

Destructors

A **destructor** is a member that implements the actions required to destruct an instance of a class. Destructors cannot have parameters, they cannot have accessibility modifiers, and they cannot be invoked explicitly. The destructor for an instance is invoked automatically during garbage collection.

The garbage collector is allowed wide latitude in deciding when to collect objects and run destructors. Specifically, the timing of destructor invocations is not deterministic, and destructors may be executed on any thread. For these and other reasons, classes should implement destructors only when no other solutions are feasible.

The `using` statement provides a better approach to object destruction.

Structs

Like classes, **structs** are data structures that can contain data members and function members, but unlike classes, structs are value types and do not require heap allocation. A variable of a struct type directly stores the data of the struct, whereas a variable of a class type stores a reference to a dynamically allocated object. Struct types do not support user-specified inheritance, and all struct types implicitly inherit from type `object`.

Structs are particularly useful for small data structures that have value semantics. Complex numbers, points in a coordinate system, or key-value pairs in a dictionary are all good examples of structs. The use of structs rather than classes for small data structures can make a large difference in the number of memory allocations an application performs. For example, the following program creates and initializes an array of 100 points. With `Point` implemented as a class, 101 separate objects are instantiated—one for the array and one each for the 100 elements.

```

class Point
{
    public int x, y;

    public Point(int x, int y) {
        this.x = x;
        this.y = y;
    }
}

class Test
{
    static void Main() {
        Point[] points = new Point[100];
        for (int i = 0; i < 100; i++) points[i] = new Point(i, i);
    }
}

```

An alternative is to make `Point` a struct.

```

struct Point
{
    public int x, y;

    public Point(int x, int y) {
        this.x = x;
        this.y = y;
    }
}

```

Now, only one object is instantiated—the one for the array—and the `Point` instances are stored in-line in the array.

Struct constructors are invoked with the `new` operator, but that does not imply that memory is being allocated. Instead of dynamically allocating an object and returning a reference to it, a struct constructor simply returns the struct value itself (typically in a temporary location on the stack), and this value is then copied as necessary.

With classes, it is possible for two variables to reference the same object and thus possible for operations on one variable to affect the object referenced by the other variable. With structs, the variables each have their own copy of the data, and it is not possible for operations on one to affect the other. For example, the output produced by the following code fragment depends on whether `Point` is a class or a struct.

```

Point a = new Point(10, 10);
Point b = a;
a.x = 20;
Console.WriteLine(b.x);

```

If `Point` is a class, the output is `20` because `a` and `b` reference the same object. If `Point` is a struct, the output is `10` because the assignment of `a` to `b` creates a copy of the value, and this copy is unaffected by the subsequent assignment to `a.x`.

The previous example highlights two of the limitations of structs. First, copying an entire struct is typically less efficient than copying an object reference, so assignment and value parameter passing can be more expensive with structs than with reference types. Second, except for `ref` and `out` parameters, it is not possible to create references to structs, which rules out their usage in a number of situations.

Arrays

An **array** is a data structure that contains a number of variables that are accessed through computed indices. The variables contained in an array, also called the **elements** of the array, are all of the same type, and this type is called the **element type** of the array.

Array types are reference types, and the declaration of an array variable simply sets aside space for a reference to an array instance. Actual array instances are created dynamically at run-time using the `new` operator. The `new` operation specifies the **length** of the new array instance, which is then fixed for the lifetime of the instance. The indices of the elements of an array range from `0` to `Length - 1`. The `new` operator automatically initializes the elements of an array to their default value, which, for example, is zero for all numeric types and `null` for all reference types.

The following example creates an array of `int` elements, initializes the array, and prints out the contents of the array.

```
using System;

class Test
{
    static void Main() {
        int[] a = new int[10];
        for (int i = 0; i < a.Length; i++) {
            a[i] = i * i;
        }
        for (int i = 0; i < a.Length; i++) {
            Console.WriteLine("a[{0}] = {1}", i, a[i]);
        }
    }
}
```

This example creates and operates on a **single-dimensional array**. C# also supports **multi-dimensional arrays**. The number of dimensions of an array type, also known as the **rank** of the array type, is one plus the number of commas written between the square brackets of the array type. The following example allocates a one-dimensional, a two-dimensional, and a three-dimensional array.

```
int[] a1 = new int[10];
int[,] a2 = new int[10, 5];
int[,,] a3 = new int[10, 5, 2];
```

The `a1` array contains 10 elements, the `a2` array contains 50 (10×5) elements, and the `a3` array contains 100 ($10 \times 5 \times 2$) elements.

The element type of an array can be any type, including an array type. An array with elements of an array type is sometimes called a **jagged array** because the lengths of the element arrays do not all have to be the same. The following example allocates an array of arrays of `int`:

```
int[][] a = new int[3][];
a[0] = new int[10];
a[1] = new int[5];
a[2] = new int[20];
```

The first line creates an array with three elements, each of type `int[]` and each with an initial value of `null`. The subsequent lines then initialize the three elements with references to individual array instances of varying lengths.

The `new` operator permits the initial values of the array elements to be specified using an **array initializer**, which is a list of expressions written between the delimiters `{` and `}`. The following example allocates and

initializes an `int[]` with three elements.

```
int[] a = new int[] {1, 2, 3};
```

Note that the length of the array is inferred from the number of expressions between `{` and `}`. Local variable and field declarations can be shortened further such that the array type does not have to be restated.

```
int[] a = {1, 2, 3};
```

Both of the previous examples are equivalent to the following:

```
int[] t = new int[3];  
t[0] = 1;  
t[1] = 2;  
t[2] = 3;  
int[] a = t;
```

Interfaces

An *interface* defines a contract that can be implemented by classes and structs. An interface can contain methods, properties, events, and indexers. An interface does not provide implementations of the members it defines—it merely specifies the members that must be supplied by classes or structs that implement the interface.

Interfaces may employ *multiple inheritance*. In the following example, the interface `IComboBox` inherits from both `ITextBox` and `IListBox`.

```
interface IControl  
{  
    void Paint();  
}  
  
interface ITextBox: IControl  
{  
    void SetText(string text);  
}  
  
interface IListBox: IControl  
{  
    void SetItems(string[] items);  
}  
  
interface IComboBox: ITextBox, IListBox {}
```

Classes and structs can implement multiple interfaces. In the following example, the class `EditBox` implements both `IControl` and `IDataBound`.

```
interface IDataBound
{
    void Bind(Binder b);
}

public class EditBox: IControl, IDataBound
{
    public void Paint() {...}
    public void Bind(Binder b) {...}
}
```

When a class or struct implements a particular interface, instances of that class or struct can be implicitly converted to that interface type. For example

```
EditBox editBox = new EditBox();
IControl control = editBox;
IDataBound dataBound = editBox;
```

In cases where an instance is not statically known to implement a particular interface, dynamic type casts can be used. For example, the following statements use dynamic type casts to obtain an object's `IControl` and `IDataBound` interface implementations. Because the actual type of the object is `EditBox`, the casts succeed.

```
object obj = new EditBox();
IControl control = (IControl)obj;
IDataBound dataBound = (IDataBound)obj;
```

In the previous `EditBox` class, the `Paint` method from the `IControl` interface and the `Bind` method from the `IDataBound` interface are implemented using `public` members. C# also supports *explicit interface member implementations*, using which the class or struct can avoid making the members `public`. An explicit interface member implementation is written using the fully qualified interface member name. For example, the `EditBox` class could implement the `IControl.Paint` and `IDataBound.Bind` methods using explicit interface member implementations as follows.

```
public class EditBox: IControl, IDataBound
{
    void IControl.Paint() {...}
    void IDataBound.Bind(Binder b) {...}
}
```

Explicit interface members can only be accessed via the interface type. For example, the implementation of `IControl.Paint` provided by the previous `EditBox` class can only be invoked by first converting the `EditBox` reference to the `IControl` interface type.

```
EditBox editBox = new EditBox();
editBox.Paint();           // Error, no such method
IControl control = editBox;
control.Paint();           // Ok
```

Enums

An *enum type* is a distinct value type with a set of named constants. The following example declares and uses an enum type named `Color` with three constant values, `Red`, `Green`, and `Blue`.

```

using System;

enum Color
{
    Red,
    Green,
    Blue
}

class Test
{
    static void PrintColor(Color color) {
        switch (color) {
            case Color.Red:
                Console.WriteLine("Red");
                break;
            case Color.Green:
                Console.WriteLine("Green");
                break;
            case Color.Blue:
                Console.WriteLine("Blue");
                break;
            default:
                Console.WriteLine("Unknown color");
                break;
        }
    }

    static void Main() {
        Color c = Color.Red;
        PrintColor(c);
        PrintColor(Color.Blue);
    }
}

```

Each enum type has a corresponding integral type called the *underlying type* of the enum type. An enum type that does not explicitly declare an underlying type has an underlying type of `int`. An enum type's storage format and range of possible values are determined by its underlying type. The set of values that an enum type can take on is not limited by its enum members. In particular, any value of the underlying type of an enum can be cast to the enum type and is a distinct valid value of that enum type.

The following example declares an enum type named `Alignment` with an underlying type of `sbyte`.

```

enum Alignment: sbyte
{
    Left = -1,
    Center = 0,
    Right = 1
}

```

As shown by the previous example, an enum member declaration can include a constant expression that specifies the value of the member. The constant value for each enum member must be in the range of the underlying type of the enum. When an enum member declaration does not explicitly specify a value, the member is given the value zero (if it is the first member in the enum type) or the value of the textually preceding enum member plus one.

Enum values can be converted to integral values and vice versa using type casts. For example

```

int i = (int)Color.Blue;      // int i = 2;
Color c = (Color)2;          // Color c = Color.Blue;

```

The default value of any enum type is the integral value zero converted to the enum type. In cases where variables are automatically initialized to a default value, this is the value given to variables of enum types. In order for the default value of an enum type to be easily available, the literal `0` implicitly converts to any enum type. Thus, the following is permitted.

```
Color c = 0;
```

Delegates

A *delegate type* represents references to methods with a particular parameter list and return type. Delegates make it possible to treat methods as entities that can be assigned to variables and passed as parameters. Delegates are similar to the concept of function pointers found in some other languages, but unlike function pointers, delegates are object-oriented and type-safe.

The following example declares and uses a delegate type named `Function`.

```
using System;

delegate double Function(double x);

class Multiplier
{
    double factor;

    public Multiplier(double factor) {
        this.factor = factor;
    }

    public double Multiply(double x) {
        return x * factor;
    }
}

class Test
{
    static double Square(double x) {
        return x * x;
    }

    static double[] Apply(double[] a, Function f) {
        double[] result = new double[a.Length];
        for (int i = 0; i < a.Length; i++) result[i] = f(a[i]);
        return result;
    }

    static void Main() {
        double[] a = {0.0, 0.5, 1.0};
        double[] squares = Apply(a, Square);
        double[] sines = Apply(a, Math.Sin);
        Multiplier m = new Multiplier(2.0);
        double[] doubles = Apply(a, m.Multiply);
    }
}
```

An instance of the `Function` delegate type can reference any method that takes a `double` argument and returns a `double` value. The `Apply` method applies a given `Function` to the elements of a `double[]`, returning a `double[]` with the results. In the `Main` method, `Apply` is used to apply three different functions to a `double[]`.

A delegate can reference either a static method (such as `Square` or `Math.Sin` in the previous example) or an instance method (such as `m.Multiply` in the previous example). A delegate that references an instance method

also references a particular object, and when the instance method is invoked through the delegate, that object becomes `this` in the invocation.

Delegates can also be created using anonymous functions, which are "inline methods" that are created on the fly. Anonymous functions can see the local variables of the surrounding methods. Thus, the multiplier example above can be written more easily without using a `Multiplier` class:

```
double[] doubles = Apply(a, (double x) => x * 2.0);
```

An interesting and useful property of a delegate is that it does not know or care about the class of the method it references; all that matters is that the referenced method has the same parameters and return type as the delegate.

Attributes

Types, members, and other entities in a C# program support modifiers that control certain aspects of their behavior. For example, the accessibility of a method is controlled using the `public`, `protected`, `internal`, and `private` modifiers. C# generalizes this capability such that user-defined types of declarative information can be attached to program entities and retrieved at run-time. Programs specify this additional declarative information by defining and using *attributes*.

The following example declares a `HelpAttribute` attribute that can be placed on program entities to provide links to their associated documentation.

```
using System;

public class HelpAttribute: Attribute
{
    string url;
    string topic;

    public HelpAttribute(string url) {
        this.url = url;
    }

    public string Url {
        get { return url; }
    }

    public string Topic {
        get { return topic; }
        set { topic = value; }
    }
}
```

All attribute classes derive from the `System.Attribute` base class provided by the .NET Framework. Attributes can be applied by giving their name, along with any arguments, inside square brackets just before the associated declaration. If an attribute's name ends in `Attribute`, that part of the name can be omitted when the attribute is referenced. For example, the `HelpAttribute` attribute can be used as follows.

```
[Help("http://msdn.microsoft.com/.../MyClass.htm")]
public class Widget
{
    [Help("http://msdn.microsoft.com/.../MyClass.htm", Topic = "Display")]
    public void Display(string text) {}
}
```

This example attaches a `HelpAttribute` to the `Widget` class and another `HelpAttribute` to the `Display` method in the class. The public constructors of an attribute class control the information that must be provided when the attribute is attached to a program entity. Additional information can be provided by referencing public read-write properties of the attribute class (such as the reference to the `Topic` property previously).

The following example shows how attribute information for a given program entity can be retrieved at run-time using reflection.

```
using System;
using System.Reflection;

class Test
{
    static void ShowHelp(MemberInfo member) {
        HelpAttribute a = Attribute.GetCustomAttribute(member,
            typeof(HelpAttribute)) as HelpAttribute;
        if (a == null) {
            Console.WriteLine("No help for {0}", member);
        }
        else {
            Console.WriteLine("Help for {0}:", member);
            Console.WriteLine("  Url={0}, Topic={1}", a.Url, a.Topic);
        }
    }

    static void Main() {
        ShowHelp(typeof(Widget));
        ShowHelp(typeof(Widget).GetMethod("Display"));
    }
}
```

When a particular attribute is requested through reflection, the constructor for the attribute class is invoked with the information provided in the program source, and the resulting attribute instance is returned. If additional information was provided through properties, those properties are set to the given values before the attribute instance is returned.

Lexical structure

12/28/2021 • 33 minutes to read • [Edit Online](#)

Programs

A C# **program** consists of one or more **source files**, known formally as **compilation units** ([Compilation units](#)). A source file is an ordered sequence of Unicode characters. Source files typically have a one-to-one correspondence with files in a file system, but this correspondence is not required. For maximal portability, it is recommended that files in a file system be encoded with the UTF-8 encoding.

Conceptually speaking, a program is compiled using three steps:

1. Transformation, which converts a file from a particular character repertoire and encoding scheme into a sequence of Unicode characters.
2. Lexical analysis, which translates a stream of Unicode input characters into a stream of tokens.
3. Syntactic analysis, which translates the stream of tokens into executable code.

Grammars

This specification presents the syntax of the C# programming language using two grammars. The **lexical grammar** ([Lexical grammar](#)) defines how Unicode characters are combined to form line terminators, white space, comments, tokens, and pre-processing directives. The **syntactic grammar** ([Syntactic grammar](#)) defines how the tokens resulting from the lexical grammar are combined to form C# programs.

Grammar notation

The lexical and syntactic grammars are presented in Backus-Naur form using the notation of the ANTLR grammar tool.

Lexical grammar

The lexical grammar of C# is presented in [Lexical analysis](#), [Tokens](#), and [Pre-processing directives](#). The terminal symbols of the lexical grammar are the characters of the Unicode character set, and the lexical grammar specifies how characters are combined to form tokens ([Tokens](#)), white space ([White space](#)), comments ([Comments](#)), and pre-processing directives ([Pre-processing directives](#)).

Every source file in a C# program must conform to the *input* production of the lexical grammar ([Lexical analysis](#)).

Syntactic grammar

The syntactic grammar of C# is presented in the chapters and appendices that follow this chapter. The terminal symbols of the syntactic grammar are the tokens defined by the lexical grammar, and the syntactic grammar specifies how tokens are combined to form C# programs.

Every source file in a C# program must conform to the *compilation_unit* production of the syntactic grammar ([Compilation units](#)).

Lexical analysis

The *input* production defines the lexical structure of a C# source file. Each source file in a C# program must conform to this lexical grammar production.

```

input
    : input_section?
    ;

input_section
    : input_section_part+
    ;

input_section_part
    : input_element* new_line
    | pp_directive
    ;

input_element
    : whitespace
    | comment
    | token
    ;

```

Five basic elements make up the lexical structure of a C# source file: Line terminators ([Line terminators](#)), white space ([White space](#)), comments ([Comments](#)), tokens ([Tokens](#)), and pre-processing directives ([Pre-processing directives](#)). Of these basic elements, only tokens are significant in the syntactic grammar of a C# program ([Syntactic grammar](#)).

The lexical processing of a C# source file consists of reducing the file into a sequence of tokens which becomes the input to the syntactic analysis. Line terminators, white space, and comments can serve to separate tokens, and pre-processing directives can cause sections of the source file to be skipped, but otherwise these lexical elements have no impact on the syntactic structure of a C# program.

In the case of interpolated string literals ([Interpolated string literals](#)) a single token is initially produced by lexical analysis, but is broken up into several input elements which are repeatedly subjected to lexical analysis until all interpolated string literals have been resolved. The resulting tokens then serve as input to the syntactic analysis.

When several lexical grammar productions match a sequence of characters in a source file, the lexical processing always forms the longest possible lexical element. For example, the character sequence `//` is processed as the beginning of a single-line comment because that lexical element is longer than a single `/` token.

Line terminators

Line terminators divide the characters of a C# source file into lines.

```

new_line
    : '<Carriage return character (U+000D)>'
    | '<Line feed character (U+000A)>'
    | '<Carriage return character (U+000D) followed by line feed character (U+000A)>'
    | '<Next line character (U+0085)>'
    | '<Line separator character (U+2028)>'
    | '<Paragraph separator character (U+2029)>'
    ;

```

For compatibility with source code editing tools that add end-of-file markers, and to enable a source file to be viewed as a sequence of properly terminated lines, the following transformations are applied, in order, to every source file in a C# program:

- If the last character of the source file is a Control-Z character (`U+001A`), this character is deleted.
- A carriage-return character (`U+000D`) is added to the end of the source file if that source file is non-empty and if the last character of the source file is not a carriage return (`U+000D`), a line feed (`U+000A`), a line separator (`U+2028`), or a paragraph separator (`U+2029`).

Comments

Two forms of comments are supported: single-line comments and delimited comments. *Single-line comments* start with the characters `//` and extend to the end of the source line. *Delimited comments* start with the characters `/*` and end with the characters `*/`. Delimited comments may span multiple lines.

```
comment
  : single_line_comment
  | delimited_comment
  ;

single_line_comment
  : '//' input_character*
  ;

input_character
  : '<Any Unicode character except a new_line_character>'
  ;

new_line_character
  : '<Carriage return character (U+000D)>'
  | '<Line feed character (U+000A)>'
  | '<Next line character (U+0085)>'
  | '<Line separator character (U+2028)>'
  | '<Paragraph separator character (U+2029)>'
  ;

delimited_comment
  : '/*' delimited_comment_section* asterisk+ '/'
  ;

delimited_comment_section
  : '/'
  | asterisk* not_slash_or_asterisk
  ;

asterisk
  : '*'
  ;

not_slash_or_asterisk
  : '<Any Unicode character except / or *>'
  ;
```

Comments do not nest. The character sequences `/*` and `*/` have no special meaning within a `//` comment, and the character sequences `//` and `/*` have no special meaning within a delimited comment.

Comments are not processed within character and string literals.

The example

```
/* Hello, world program
   This program writes "hello, world" to the console
*/
class Hello
{
    static void Main() {
        System.Console.WriteLine("hello, world");
    }
}
```

includes a delimited comment.

The example

```
// Hello, world program
// This program writes "hello, world" to the console
//
class Hello // any name will do for this class
{
    static void Main() { // this method must be named "Main"
        System.Console.WriteLine("hello, world");
    }
}
```

shows several single-line comments.

White space

White space is defined as any character with Unicode class Zs (which includes the space character) as well as the horizontal tab character, the vertical tab character, and the form feed character.

```
whitespace
: '<Any character with Unicode class Zs>'
| '<Horizontal tab character (U+0009)>'
| '<Vertical tab character (U+000B)>'
| '<Form feed character (U+000C)>'
;
```

Tokens

There are several kinds of tokens: identifiers, keywords, literals, operators, and punctuators. White space and comments are not tokens, though they act as separators for tokens.

```
token
: identifier
| keyword
| integer_literal
| real_literal
| character_literal
| string_literal
| interpolated_string_literal
| operator_or_punctuator
;
```

Unicode character escape sequences

A Unicode character escape sequence represents a Unicode character. Unicode character escape sequences are processed in identifiers ([Identifiers](#)), character literals ([Character literals](#)), and regular string literals ([String literals](#)). A Unicode character escape is not processed in any other location (for example, to form an operator, punctuator, or keyword).

```
unicode_escape_sequence
: '\\u' hex_digit hex_digit hex_digit hex_digit
| '\\U' hex_digit hex_digit hex_digit hex_digit hex_digit hex_digit hex_digit hex_digit
;
```

A Unicode escape sequence represents the single Unicode character formed by the hexadecimal number following the "`\u`" or "`\U`" characters. Since C# uses a 16-bit encoding of Unicode code points in characters and string values, a Unicode character in the range U+10000 to U+10FFFF is not permitted in a character literal and is represented using a Unicode surrogate pair in a string literal. Unicode characters with code points above 0x10FFFF are not supported.

Multiple translations are not performed. For instance, the string literal "\u005Cu005C" is equivalent to "\u005C" rather than "\\". The Unicode value \u005C is the character "\\".

The example

```
class Class1
{
    static void Test(bool \u0066) {
        char c = '\u0066';
        if (\u0066)
            System.Console.WriteLine(c.ToString());
    }
}
```

shows several uses of \u0066, which is the escape sequence for the letter "f". The program is equivalent to

```
class Class1
{
    static void Test(bool f) {
        char c = 'f';
        if (f)
            System.Console.WriteLine(c.ToString());
    }
}
```

Identifiers

The rules for identifiers given in this section correspond exactly to those recommended by the Unicode Standard Annex 31, except that underscore is allowed as an initial character (as is traditional in the C programming language), Unicode escape sequences are permitted in identifiers, and the "@" character is allowed as a prefix to enable keywords to be used as identifiers.

```

identifier
    : available_identifier
    | '@' identifier_or_keyword
    ;

available_identifier
    : '<An identifier_or_keyword that is not a keyword>'
    ;

identifier_or_keyword
    : identifier_start_character identifier_part_character*
    ;

identifier_start_character
    : letter_character
    | '_'
    ;

identifier_part_character
    : letter_character
    | decimal_digit_character
    | connecting_character
    | combining_character
    | formatting_character
    ;

letter_character
    : '<A Unicode character of classes Lu, Ll, Lt, Lm, Lo, or Nl>'
    | '<A unicode_escape_sequence representing a character of classes Lu, Ll, Lt, Lm, Lo, or Nl>'
    ;

combining_character
    : '<A Unicode character of classes Mn or Mc>'
    | '<A unicode_escape_sequence representing a character of classes Mn or Mc>'
    ;

decimal_digit_character
    : '<A Unicode character of the class Nd>'
    | '<A unicode_escape_sequence representing a character of the class Nd>'
    ;

connecting_character
    : '<A Unicode character of the class Pc>'
    | '<A unicode_escape_sequence representing a character of the class Pc>'
    ;

formatting_character
    : '<A Unicode character of the class Cf>'
    | '<A unicode_escape_sequence representing a character of the class Cf>'
    ;

```

For information on the Unicode character classes mentioned above, see The Unicode Standard, Version 3.0, section 4.5.

Examples of valid identifiers include "identifier1", "_identifier2", and "@if".

An identifier in a conforming program must be in the canonical format defined by Unicode Normalization Form C, as defined by Unicode Standard Annex 15. The behavior when encountering an identifier not in Normalization Form C is implementation-defined; however, a diagnostic is not required.

The prefix "@" enables the use of keywords as identifiers, which is useful when interfacing with other programming languages. The character @ is not actually part of the identifier, so the identifier might be seen in other languages as a normal identifier, without the prefix. An identifier with an @ prefix is called a *verbatim identifier*. Use of the @ prefix for identifiers that are not keywords is permitted, but strongly discouraged as a

matter of style.

The example:

```
class @class
{
    public static void @static(bool @bool) {
        if (@bool)
            System.Console.WriteLine("true");
        else
            System.Console.WriteLine("false");
    }
}

class Class1
{
    static void M() {
        cl\u0061ss.st\u0061tic(true);
    }
}
```

defines a class named "`class`" with a static method named "`static`" that takes a parameter named "`bool`". Note that since Unicode escapes are not permitted in keywords, the token "`cl\u0061ss`" is an identifier, and is the same identifier as "`@class`".

Two identifiers are considered the same if they are identical after the following transformations are applied, in order:

- The prefix "`@`", if used, is removed.
- Each *unicode_escape_sequence* is transformed into its corresponding Unicode character.
- Any *formatting_characters* are removed.

Identifiers containing two consecutive underscore characters (`U+005F`) are reserved for use by the implementation. For example, an implementation might provide extended keywords that begin with two underscores.

Keywords

A **keyword** is an identifier-like sequence of characters that is reserved, and cannot be used as an identifier except when prefaced by the `@` character.

```
keyword
: 'abstract' | 'as'      | 'base'      | 'bool'      | 'break'
| 'byte'      | 'case'      | 'catch'     | 'char'      | 'checked'
| 'class'     | 'const'     | 'continue'  | 'decimal'   | 'default'
| 'delegate'  | 'do'        | 'double'    | 'else'      | 'enum'
| 'event'     | 'explicit'  | 'extern'    | 'false'     | 'finally'
| 'fixed'     | 'float'     | 'for'       | 'foreach'   | 'goto'
| 'if'        | 'implicit'  | 'in'        | 'int'       | 'interface'
| 'internal'  | 'is'        | 'lock'      | 'long'      | 'namespace'
| 'new'       | 'null'      | 'object'    | 'operator'  | 'out'
| 'override'  | 'params'    | 'private'   | 'protected' | 'public'
| 'readonly'  | 'ref'       | 'return'    | 'sbyte'     | 'sealed'
| 'short'     | 'sizeof'    | 'stackalloc'| 'static'    | 'string'
| 'struct'    | 'switch'    | 'this'      | 'throw'     | 'true'
| 'try'       | 'typeof'    | 'uint'      | 'ulong'     | 'unchecked'
| 'unsafe'    | 'ushort'    | 'using'     | 'virtual'   | 'void'
| 'volatile'  | 'while'
;
```

In some places in the grammar, specific identifiers have special meaning, but are not keywords. Such identifiers

are sometimes referred to as "contextual keywords". For example, within a property declaration, the "`get`" and "`set`" identifiers have special meaning ([Accessors](#)). An identifier other than `get` or `set` is never permitted in these locations, so this use does not conflict with a use of these words as identifiers. In other cases, such as with the identifier "`var`" in implicitly typed local variable declarations ([Local variable declarations](#)), a contextual keyword can conflict with declared names. In such cases, the declared name takes precedence over the use of the identifier as a contextual keyword.

Literals

A *literal* is a source code representation of a value.

```
literal
: boolean_literal
| integer_literal
| real_literal
| character_literal
| string_literal
| null_literal
;
```

Boolean literals

There are two boolean literal values: `true` and `false`.

```
boolean_literal
: 'true'
| 'false'
;
```

The type of a *boolean_literal* is `bool`.

Integer literals

Integer literals are used to write values of types `int`, `uint`, `long`, and `ulong`. Integer literals have two possible forms: decimal and hexadecimal.

```
integer_literal
: decimal_integer_literal
| hexadecimal_integer_literal
;

decimal_integer_literal
: decimal_digit+ integer_type_suffix?
;

decimal_digit
: '0' | '1' | '2' | '3' | '4' | '5' | '6' | '7' | '8' | '9'
;

integer_type_suffix
: 'U' | 'u' | 'L' | 'l' | 'UL' | 'Ul' | 'uL' | 'ul' | 'LU' | 'Lu' | 'LU' | 'lu'
;

hexadecimal_integer_literal
: '0x' hex_digit+ integer_type_suffix?
| '0X' hex_digit+ integer_type_suffix?
;

hex_digit
: '0' | '1' | '2' | '3' | '4' | '5' | '6' | '7' | '8' | '9'
| 'A' | 'B' | 'C' | 'D' | 'E' | 'F' | 'a' | 'b' | 'c' | 'd' | 'e' | 'f';
```

The type of an integer literal is determined as follows:

- If the literal has no suffix, it has the first of these types in which its value can be represented: `int`, `uint`, `long`, `ulong`.
- If the literal is suffixed by `U` or `u`, it has the first of these types in which its value can be represented: `uint`, `ulong`.
- If the literal is suffixed by `L` or `l`, it has the first of these types in which its value can be represented: `long`, `ulong`.
- If the literal is suffixed by `UL`, `Ul`, `uL`, `ul`, `LU`, `Lu`, `lU`, or `lu`, it is of type `ulong`.

If the value represented by an integer literal is outside the range of the `ulong` type, a compile-time error occurs.

As a matter of style, it is suggested that "`L`" be used instead of "`l`" when writing literals of type `long`, since it is easy to confuse the letter "`l`" with the digit "`1`".

To permit the smallest possible `int` and `long` values to be written as decimal integer literals, the following two rules exist:

- When a *decimal_integer_literal* with the value 2147483648 (2^{31}) and no *integer_type_suffix* appears as the token immediately following a unary minus operator token ([Unary minus operator](#)), the result is a constant of type `int` with the value -2147483648 (-2^{31}). In all other situations, such a *decimal_integer_literal* is of type `uint`.
- When a *decimal_integer_literal* with the value 9223372036854775808 (2^{63}) and no *integer_type_suffix* or the *integer_type_suffix* `L` or `l` appears as the token immediately following a unary minus operator token ([Unary minus operator](#)), the result is a constant of type `long` with the value -9223372036854775808 (-2^{63}). In all other situations, such a *decimal_integer_literal* is of type `ulong`.

Real literals

Real literals are used to write values of types `float`, `double`, and `decimal`.

```
real_literal
: decimal_digit+ '.' decimal_digit+ exponent_part? real_type_suffix?
| '.' decimal_digit+ exponent_part? real_type_suffix?
| decimal_digit+ exponent_part real_type_suffix?
| decimal_digit+ real_type_suffix
;

exponent_part
: 'e' sign? decimal_digit+
| 'E' sign? decimal_digit+
;

sign
: '+'
| '-'
;

real_type_suffix
: 'F' | 'f' | 'D' | 'd' | 'M' | 'm'
;
```

If no *real_type_suffix* is specified, the type of the real literal is `double`. Otherwise, the real type suffix determines the type of the real literal, as follows:

- A real literal suffixed by `F` or `f` is of type `float`. For example, the literals `1f`, `1.5f`, `1e10f`, and `123.456F` are all of type `float`.
- A real literal suffixed by `D` or `d` is of type `double`. For example, the literals `1d`, `1.5d`, `1e10d`, and `123.456D` are all of type `double`.
- A real literal suffixed by `M` or `m` is of type `decimal`. For example, the literals `1m`, `1.5m`, `1e10m`, and

`123.456M` are all of type `decimal`. This literal is converted to a `decimal` value by taking the exact value, and, if necessary, rounding to the nearest representable value using banker's rounding ([The decimal type](#)). Any scale apparent in the literal is preserved unless the value is rounded or the value is zero (in which latter case the sign and scale will be 0). Hence, the literal `2.900m` will be parsed to form the decimal with sign `0`, coefficient `2900`, and scale `3`.

If the specified literal cannot be represented in the indicated type, a compile-time error occurs.

The value of a real literal of type `float` or `double` is determined by using the IEEE "round to nearest" mode.

Note that in a real literal, decimal digits are always required after the decimal point. For example, `1.3F` is a real literal but `1.F` is not.

Character literals

A character literal represents a single character, and usually consists of a character in quotes, as in `'a'`.

Note: The ANTLR grammar notation makes the following confusing! In ANTLR, when you write `\'` it stands for a single quote `'`. And when you write `\\` it stands for a single backslash `\`. Therefore the first rule for a character literal means it starts with a single quote, then a character, then a single quote. And the eleven possible escape sequences are `\'`, `\"`, `\\`, `\0`, `\a`, `\b`, `\f`, `\n`, `\r`, `\t`, `\v`.

```
character_literal
: '\'' character '\''
;

character
: single_character
| simple_escape_sequence
| hexadecimal_escape_sequence
| unicode_escape_sequence
;

single_character
: '<Any character except \' (U+0027), \'\' (U+005C), and new_line_character>'
;

simple_escape_sequence
: '\\\'' | '\\\"' | '\\\\' | '\\0' | '\\a' | '\\b' | '\\f' | '\\n' | '\\r' | '\\t' | '\\v'
;

hexadecimal_escape_sequence
: '\\x' hex_digit hex_digit? hex_digit? hex_digit?;
```

A character that follows a backslash character (`\`) in a *character* must be one of the following characters: `'`, `"`, `\`, `0`, `a`, `b`, `f`, `n`, `r`, `t`, `u`, `U`, `x`, `v`. Otherwise, a compile-time error occurs.

A hexadecimal escape sequence represents a single Unicode character, with the value formed by the hexadecimal number following `\x`.

If the value represented by a character literal is greater than `U+FFFF`, a compile-time error occurs.

A Unicode character escape sequence ([Unicode character escape sequences](#)) in a character literal must be in the range `U+0000` to `U+FFFF`.

A simple escape sequence represents a Unicode character encoding, as described in the table below.

ESCAPE SEQUENCE	CHARACTER NAME	UNICODE ENCODING
<code>\'</code>	Single quote	<code>0x0027</code>

ESCAPE SEQUENCE	CHARACTER NAME	UNICODE ENCODING
<code>\"</code>	Double quote	<code>0x0022</code>
<code>\\</code>	Backslash	<code>0x005C</code>
<code>\0</code>	Null	<code>0x0000</code>
<code>\a</code>	Alert	<code>0x0007</code>
<code>\b</code>	Backspace	<code>0x0008</code>
<code>\f</code>	Form feed	<code>0x000C</code>
<code>\n</code>	New line	<code>0x000A</code>
<code>\r</code>	Carriage return	<code>0x000D</code>
<code>\t</code>	Horizontal tab	<code>0x0009</code>
<code>\v</code>	Vertical tab	<code>0x000B</code>

The type of a *character_literal* is `char`.

String literals

C# supports two forms of string literals: *regular string literals* and *verbatim string literals*.

A regular string literal consists of zero or more characters enclosed in double quotes, as in `"hello"`, and may include both simple escape sequences (such as `\t` for the tab character), and hexadecimal and Unicode escape sequences.

A verbatim string literal consists of an `@` character followed by a double-quote character, zero or more characters, and a closing double-quote character. A simple example is `@"hello"`. In a verbatim string literal, the characters between the delimiters are interpreted verbatim, the only exception being a *quote_escape_sequence*. In particular, simple escape sequences, and hexadecimal and Unicode escape sequences are not processed in verbatim string literals. A verbatim string literal may span multiple lines.

```

string_literal
: regular_string_literal
| verbatim_string_literal
;

regular_string_literal
: '"' regular_string_literal_character* '"'
;

regular_string_literal_character
: single_regular_string_literal_character
| simple_escape_sequence
| hexadecimal_escape_sequence
| unicode_escape_sequence
;

single_regular_string_literal_character
: '<Any character except " (U+0022), \\ (U+005C), and new_line_character>'
;

verbatim_string_literal
: '@"' verbatim_string_literal_character* '"'
;

verbatim_string_literal_character
: single_verbatim_string_literal_character
| quote_escape_sequence
;

single_verbatim_string_literal_character
: '<any character except ">'
;

quote_escape_sequence
: '""'
;

```

A character that follows a backslash character (`\`) in a *regular_string_literal_character* must be one of the following characters: `'`, `"`, `\`, `0`, `a`, `b`, `f`, `n`, `r`, `t`, `u`, `U`, `x`, `v`. Otherwise, a compile-time error occurs.

The example

```

string a = "hello, world";           // hello, world
string b = @"hello, world";          // hello, world

string c = "hello \t world";          // hello      world
string d = @"hello \t world";          // hello \t world

string e = "Joe said \"Hello\" to me"; // Joe said "Hello" to me
string f = @"Joe said ""Hello"" to me"; // Joe said "Hello" to me

string g = "\\server\\share\\file.txt"; // \\server\share\file.txt
string h = @"\\server\share\file.txt";  // \\server\share\file.txt

string i = "one\r\ntwo\r\nthree";
string j = @"one
two
three";

```

shows a variety of string literals. The last string literal, `j`, is a verbatim string literal that spans multiple lines. The characters between the quotation marks, including white space such as new line characters, are preserved verbatim.

Since a hexadecimal escape sequence can have a variable number of hex digits, the string literal `"\x123"` contains a single character with hex value 123. To create a string containing the character with hex value 12 followed by the character 3, one could write `"\x00123"` or `"\x12" + "3"` instead.

The type of a *string literal* is `string`.

Each string literal does not necessarily result in a new string instance. When two or more string literals that are equivalent according to the string equality operator ([String equality operators](#)) appear in the same program, these string literals refer to the same string instance. For instance, the output produced by

```
class Test
{
    static void Main() {
        object a = "hello";
        object b = "hello";
        System.Console.WriteLine(a == b);
    }
}
```

is `True` because the two literals refer to the same string instance.

Interpolated string literals

Interpolated string literals are similar to string literals, but contain holes delimited by `{` and `}`, wherein expressions can occur. At runtime, the expressions are evaluated with the purpose of having their textual forms substituted into the string at the place where the hole occurs. The syntax and semantics of string interpolation are described in section ([Interpolated strings](#)).

Like string literals, interpolated string literals can be either regular or verbatim. Interpolated regular string literals are delimited by `$"` and `"`, and interpolated verbatim string literals are delimited by `$@"` and `"`.

Like other literals, lexical analysis of an interpolated string literal initially results in a single token, as per the grammar below. However, before syntactic analysis, the single token of an interpolated string literal is broken into several tokens for the parts of the string enclosing the holes, and the input elements occurring in the holes are lexically analysed again. This may in turn produce more interpolated string literals to be processed, but, if lexically correct, will eventually lead to a sequence of tokens for syntactic analysis to process.

```
interpolated_string_literal

| '[' verbatim_balanced_text ']'
| '{' verbatim_balanced_text '}'
;

single_verbatim_balanced_text_character
: '<Any character except / (U+002F), @ (U+0040), \" (U+0022), $ (U+0024), ( (U+0028), ) (U+0029), [
(U+005B), ] (U+005D), { (U+007B) and } (U+007D)>'
| '</ (U+002F), if not directly followed by / (U+002F) or * (U+002A)>'
;

```

An *interpolated_string_literal* token is reinterpreted as multiple tokens and other input elements as follows, in

order of occurrence in the *interpolated_string_literal*.

- Occurrences of the following are reinterpreted as separate individual tokens: the leading `$` sign, *interpolated_regular_string_whole*, *interpolated_regular_string_start*, *interpolated_regular_string_mid*, *interpolated_regular_string_end*, *interpolated_verbatim_string_whole*, *interpolated_verbatim_string_start*, *interpolated_verbatim_string_mid* and *interpolated_verbatim_string_end*.
- Occurrences of *regular_balanced_text* and *verbatim_balanced_text* between these are reprocessed as an *input_section* ([Lexical analysis](#)) and are reinterpreted as the resulting sequence of input elements. These may in turn include interpolated string literal tokens to be reinterpreted.

Syntactic analysis will recombine the tokens into an *interpolated_string_expression* ([Interpolated strings](#)).

Examples TODO

The null literal

```
null_literal
: 'null'
;
```

The *null_literal* can be implicitly converted to a reference type or nullable type.

Operators and punctuators

There are several kinds of operators and punctuators. Operators are used in expressions to describe operations involving one or more operands. For example, the expression `a + b` uses the `+` operator to add the two operands `a` and `b`. Punctuators are for grouping and separating.

```
operator_or_punctuator
: '{' | '}' | '[' | ']' | '(' | ')' | '.' | ',' | ':' | ';'
| '+' | '-' | '*' | '/' | '%' | '&' | '|' | '^' | '!' | '~'
| '=' | '<' | '>' | '?' | '??' | '::' | '++' | '--' | '&&' | '||'
| '->' | '==' | '!=' | '<=' | '>=' | '+=' | '-=' | '*=' | '/=' | '%='
| '&=' | '|=' | '^=' | '<<' | '<<=' | '>='
;

right_shift
: '>>'
;

right_shift_assignment
: '>>='
;
```

The vertical bar in the *right_shift* and *right_shift_assignment* productions are used to indicate that, unlike other productions in the syntactic grammar, no characters of any kind (not even whitespace) are allowed between the tokens. These productions are treated specially in order to enable the correct handling of *type_parameter_lists* ([Type parameters](#)).

Pre-processing directives

The pre-processing directives provide the ability to conditionally skip sections of source files, to report error and warning conditions, and to delineate distinct regions of source code. The term "pre-processing directives" is used only for consistency with the C and C++ programming languages. In C#, there is no separate pre-processing step; pre-processing directives are processed as part of the lexical analysis phase.

```
pp_directive
: pp_declaration
| pp_conditional
| pp_line
| pp_diagnostic
| pp_region
| pp_pragma
;
```

The following pre-processing directives are available:

- `#define` and `#undef`, which are used to define and undefine, respectively, conditional compilation symbols ([Declaration directives](#)).
- `#if`, `#elif`, `#else`, and `#endif`, which are used to conditionally skip sections of source code ([Conditional compilation directives](#)).
- `#line`, which is used to control line numbers emitted for errors and warnings ([Line directives](#)).
- `#error` and `#warning`, which are used to issue errors and warnings, respectively ([Diagnostic directives](#)).
- `#region` and `#endregion`, which are used to explicitly mark sections of source code ([Region directives](#)).
- `#pragma`, which is used to specify optional contextual information to the compiler ([Pragma directives](#)).

A pre-processing directive always occupies a separate line of source code and always begins with a `#` character and a pre-processing directive name. White space may occur before the `#` character and between the `#` character and the directive name.

A source line containing a `#define`, `#undef`, `#if`, `#elif`, `#else`, `#endif`, `#line`, or `#endregion` directive may end with a single-line comment. Delimited comments (the `/* */` style of comments) are not permitted on source lines containing pre-processing directives.

Pre-processing directives are not tokens and are not part of the syntactic grammar of C#. However, pre-processing directives can be used to include or exclude sequences of tokens and can in that way affect the meaning of a C# program. For example, when compiled, the program:

```
#define A
#undef B

class C
{
    #if A
        void F() {}
    #else
        void G() {}
    #endif

    #if B
        void H() {}
    #else
        void I() {}
    #endif
}
```

results in the exact same sequence of tokens as the program:

```
class C
{
    void F() {}
    void I() {}
}
```

Thus, whereas lexically, the two programs are quite different, syntactically, they are identical.

Conditional compilation symbols

The conditional compilation functionality provided by the `#if`, `#elif`, `#else`, and `#endif` directives is controlled through pre-processing expressions ([Pre-processing expressions](#)) and conditional compilation symbols.

```
conditional_symbol
: '<Any identifier_or_keyword except true or false>'
;
```

A conditional compilation symbol has two possible states: ***defined*** or ***undefined***. At the beginning of the lexical processing of a source file, a conditional compilation symbol is undefined unless it has been explicitly defined by an external mechanism (such as a command-line compiler option). When a `#define` directive is processed, the conditional compilation symbol named in that directive becomes defined in that source file. The symbol remains defined until an `#undef` directive for that same symbol is processed, or until the end of the source file is reached. An implication of this is that `#define` and `#undef` directives in one source file have no effect on other source files in the same program.

When referenced in a pre-processing expression, a defined conditional compilation symbol has the boolean value `true`, and an undefined conditional compilation symbol has the boolean value `false`. There is no requirement that conditional compilation symbols be explicitly declared before they are referenced in pre-processing expressions. Instead, undeclared symbols are simply undefined and thus have the value `false`.

The name space for conditional compilation symbols is distinct and separate from all other named entities in a C# program. Conditional compilation symbols can only be referenced in `#define` and `#undef` directives and in pre-processing expressions.

Pre-processing expressions

Pre-processing expressions can occur in `#if` and `#elif` directives. The operators `!`, `==`, `!=`, `&&` and `||` are permitted in pre-processing expressions, and parentheses may be used for grouping.

```

pp_expression
: whitespace? pp_or_expression whitespace?
;

pp_or_expression
: pp_and_expression
| pp_or_expression whitespace? '||' whitespace? pp_and_expression
;

pp_and_expression
: pp_equality_expression
| pp_and_expression whitespace? '&&' whitespace? pp_equality_expression
;

pp_equality_expression
: pp_unary_expression
| pp_equality_expression whitespace? '==' whitespace? pp_unary_expression
| pp_equality_expression whitespace? '!=' whitespace? pp_unary_expression
;

pp_unary_expression
: pp_primary_expression
| '!' whitespace? pp_unary_expression
;

pp_primary_expression
: 'true'
| 'false'
| conditional_symbol
| '(' whitespace? pp_expression whitespace? ')'
;

```

When referenced in a pre-processing expression, a defined conditional compilation symbol has the boolean value `true`, and an undefined conditional compilation symbol has the boolean value `false`.

Evaluation of a pre-processing expression always yields a boolean value. The rules of evaluation for a pre-processing expression are the same as those for a constant expression ([Constant expressions](#)), except that the only user-defined entities that can be referenced are conditional compilation symbols.

Declaration directives

The declaration directives are used to define or undefine conditional compilation symbols.

```

pp_declaration
: whitespace? '#' whitespace? 'define' whitespace conditional_symbol pp_new_line
| whitespace? '#' whitespace? 'undef' whitespace conditional_symbol pp_new_line
;

pp_new_line
: whitespace? single_line_comment? new_line
;

```

The processing of a `#define` directive causes the given conditional compilation symbol to become defined, starting with the source line that follows the directive. Likewise, the processing of an `#undef` directive causes the given conditional compilation symbol to become undefined, starting with the source line that follows the directive.

Any `#define` and `#undef` directives in a source file must occur before the first *token* ([Tokens](#)) in the source file; otherwise a compile-time error occurs. In intuitive terms, `#define` and `#undef` directives must precede any "real code" in the source file.

The example:

```
#define Enterprise

#if Professional || Enterprise
    #define Advanced
#endif

namespace Megacorp.Data
{
    #if Advanced
    class PivotTable {...}
    #endif
}
```

is valid because the `#define` directives precede the first token (the `namespace` keyword) in the source file.

The following example results in a compile-time error because a `#define` follows real code:

```
#define A
namespace N
{
    #define B
    #if B
    class Class1 {}
    #endif
}
```

A `#define` may define a conditional compilation symbol that is already defined, without there being any intervening `#undef` for that symbol. The example below defines a conditional compilation symbol `A` and then defines it again.

```
#define A
#define A
```

A `#undef` may "undefine" a conditional compilation symbol that is not defined. The example below defines a conditional compilation symbol `A` and then undefines it twice; although the second `#undef` has no effect, it is still valid.

```
#define A
#undef A
#undef A
```

Conditional compilation directives

The conditional compilation directives are used to conditionally include or exclude portions of a source file.

```

pp_conditional
: pp_if_section pp_elif_section* pp_else_section? pp_endif
;

pp_if_section
: whitespace? '#' whitespace? 'if' whitespace pp_expression pp_new_line conditional_section?
;

pp_elif_section
: whitespace? '#' whitespace? 'elif' whitespace pp_expression pp_new_line conditional_section?
;

pp_else_section:
| whitespace? '#' whitespace? 'else' pp_new_line conditional_section?
;

pp_endif
: whitespace? '#' whitespace? 'endif' pp_new_line
;

conditional_section
: input_section
| skipped_section
;

skipped_section
: skipped_section_part+
;

skipped_section_part
: skipped_characters? new_line
| pp_directive
;

skipped_characters
: whitespace? not_number_sign input_character*
;

not_number_sign
: '<Any input_character except #>'
;

```

As indicated by the syntax, conditional compilation directives must be written as sets consisting of, in order, an `#if` directive, zero or more `#elif` directives, zero or one `#else` directive, and an `#endif` directive. Between the directives are conditional sections of source code. Each section is controlled by the immediately preceding directive. A conditional section may itself contain nested conditional compilation directives provided these directives form complete sets.

A *pp_conditional* selects at most one of the contained *conditional_sections* for normal lexical processing:

- The *pp_expressions* of the `#if` and `#elif` directives are evaluated in order until one yields `true`. If an expression yields `true`, the *conditional_section* of the corresponding directive is selected.
- If all *pp_expressions* yield `false`, and if an `#else` directive is present, the *conditional_section* of the `#else` directive is selected.
- Otherwise, no *conditional_section* is selected.

The selected *conditional_section*, if any, is processed as a normal *input_section*: the source code contained in the section must adhere to the lexical grammar; tokens are generated from the source code in the section; and pre-processing directives in the section have the prescribed effects.

The remaining *conditional_sections*, if any, are processed as *skipped_sections*: except for pre-processing directives, the source code in the section need not adhere to the lexical grammar; no tokens are generated from

the source code in the section; and pre-processing directives in the section must be lexically correct but are not otherwise processed. Within a *conditional_section* that is being processed as a *skipped_section*, any nested *conditional_sections* (contained in nested `#if ... #endif` and `#region ... #endregion` constructs) are also processed as *skipped_sections*.

The following example illustrates how conditional compilation directives can nest:

```
#define Debug      // Debugging on
#undef Trace      // Tracing off

class PurchaseTransaction
{
    void Commit() {
        #if Debug
            CheckConsistency();
            #if Trace
                WriteToLog(this.ToString());
            #endif
        #endif
        CommitHelper();
    }
}
```

Except for pre-processing directives, skipped source code is not subject to lexical analysis. For example, the following is valid despite the unterminated comment in the `#else` section:

```
#define Debug      // Debugging on

class PurchaseTransaction
{
    void Commit() {
        #if Debug
            CheckConsistency();
        #else
            /* Do something else
        #endif
    }
}
```

Note, however, that pre-processing directives are required to be lexically correct even in skipped sections of source code.

Pre-processing directives are not processed when they appear inside multi-line input elements. For example, the program:

```
class Hello
{
    static void Main() {
        System.Console.WriteLine(@"hello,
#if Debug
    world
#else
    Nebraska
#endif
    ");
    }
}
```

results in the output:

```
hello,
#ifdef Debug
    world
#else
    Nebraska
#endif
```

In peculiar cases, the set of pre-processing directives that is processed might depend on the evaluation of the *pp_expression*. The example:

```
#if X
    /*
#else
    /* */ class Q { }
#endif
```

always produces the same token stream (`class Q { }`), regardless of whether or not `X` is defined. If `X` is defined, the only processed directives are `#if` and `#endif`, due to the multi-line comment. If `X` is undefined, then three directives (`#if`, `#else`, `#endif`) are part of the directive set.

Diagnostic directives

The diagnostic directives are used to explicitly generate error and warning messages that are reported in the same way as other compile-time errors and warnings.

```
pp_diagnostic
: whitespace? '#' whitespace? 'error' pp_message
| whitespace? '#' whitespace? 'warning' pp_message
;

pp_message
: new_line
| whitespace input_character* new_line
;
```

The example:

```
#warning Code review needed before check-in

#ifdef Debug && Retail
    #error A build can't be both debug and retail
#endif

class Test {...}
```

always produces a warning ("Code review needed before check-in"), and produces a compile-time error ("A build can't be both debug and retail") if the conditional symbols `Debug` and `Retail` are both defined. Note that a *pp_message* can contain arbitrary text; specifically, it need not contain well-formed tokens, as shown by the single quote in the word `can't`.

Region directives

The region directives are used to explicitly mark regions of source code.

```

pp_region
: pp_start_region conditional_section? pp_end_region
;

pp_start_region
: whitespace? '#' whitespace? 'region' pp_message
;

pp_end_region
: whitespace? '#' whitespace? 'endregion' pp_message
;

```

No semantic meaning is attached to a region; regions are intended for use by the programmer or by automated tools to mark a section of source code. The message specified in a `#region` or `#endregion` directive likewise has no semantic meaning; it merely serves to identify the region. Matching `#region` and `#endregion` directives may have different *pp_messages*.

The lexical processing of a region:

```

#region
...
#endregion

```

corresponds exactly to the lexical processing of a conditional compilation directive of the form:

```

#if true
...
#endif

```

Line directives

Line directives may be used to alter the line numbers and source file names that are reported by the compiler in output such as warnings and errors, and that are used by caller info attributes ([Caller info attributes](#)).

Line directives are most commonly used in meta-programming tools that generate C# source code from some other text input.

```

pp_line
: whitespace? '#' whitespace? 'line' whitespace line_indicator pp_new_line
;

line_indicator
: decimal_digit+ whitespace file_name
| decimal_digit+
| 'default'
| 'hidden'
;

file_name
: ''' file_name_character+ '''
;

file_name_character
: '<Any input_character except ">'
;

```

When no `#line` directives are present, the compiler reports true line numbers and source file names in its output. When processing a `#line` directive that includes a *line_indicator* that is not `default`, the compiler treats the line after the directive as having the given line number (and file name, if specified).

A `#line default` directive reverses the effect of all preceding `#line` directives. The compiler reports true line information for subsequent lines, precisely as if no `#line` directives had been processed.

A `#line hidden` directive has no effect on the file and line numbers reported in error messages, but does affect source level debugging. When debugging, all lines between a `#line hidden` directive and the subsequent `#line` directive (that is not `#line hidden`) have no line number information. When stepping through code in the debugger, these lines will be skipped entirely.

Note that a *file_name* differs from a regular string literal in that escape characters are not processed; the `"\"` character simply designates an ordinary backslash character within a *file_name*.

Pragma directives

The `#pragma` preprocessing directive is used to specify optional contextual information to the compiler. The information supplied in a `#pragma` directive will never change program semantics.

```
pp_pragma
    : whitespace? '#' whitespace? 'pragma' whitespace pragma_body pp_new_line
    ;

pragma_body
    : pragma_warning_body
    ;
```

C# provides `#pragma` directives to control compiler warnings. Future versions of the language may include additional `#pragma` directives. To ensure interoperability with other C# compilers, the Microsoft C# compiler does not issue compilation errors for unknown `#pragma` directives; such directives do however generate warnings.

Pragma warning

The `#pragma warning` directive is used to disable or restore all or a particular set of warning messages during compilation of the subsequent program text.

```
pragma_warning_body
    : 'warning' whitespace warning_action
    | 'warning' whitespace warning_action whitespace warning_list
    ;

warning_action
    : 'disable'
    | 'restore'
    ;

warning_list
    : decimal_digit+ (whitespace? ',' whitespace? decimal_digit+)*
    ;
```

A `#pragma warning` directive that omits the warning list affects all warnings. A `#pragma warning` directive that includes a warning list affects only those warnings that are specified in the list.

A `#pragma warning disable` directive disables all or the given set of warnings.

A `#pragma warning restore` directive restores all or the given set of warnings to the state that was in effect at the beginning of the compilation unit. Note that if a particular warning was disabled externally, a `#pragma warning restore` (whether for all or the specific warning) will not re-enable that warning.

The following example shows use of `#pragma warning` to temporarily disable the warning reported when obsoleted members are referenced, using the warning number from the Microsoft C# compiler.

```
using System;

class Program
{
    [Obsolete]
    static void Foo() {}

    static void Main() {
#pragma warning disable 612
        Foo();
#pragma warning restore 612
    }
}
```

Basic concepts

12/28/2021 • 48 minutes to read • [Edit Online](#)

Application Startup

An assembly that has an *entry point* is called an *application*. When an application is run, a new *application domain* is created. Several different instantiations of an application may exist on the same machine at the same time, and each has its own application domain.

An application domain enables application isolation by acting as a container for application state. An application domain acts as a container and boundary for the types defined in the application and the class libraries it uses. Types loaded into one application domain are distinct from the same type loaded into another application domain, and instances of objects are not directly shared between application domains. For instance, each application domain has its own copy of static variables for these types, and a static constructor for a type is run at most once per application domain. Implementations are free to provide implementation-specific policy or mechanisms for the creation and destruction of application domains.

Application startup occurs when the execution environment calls a designated method, which is referred to as the application's entry point. This entry point method is always named `Main`, and can have one of the following signatures:

```
static void Main() {...}

static void Main(string[] args) {...}

static int Main() {...}

static int Main(string[] args) {...}
```

As shown, the entry point may optionally return an `int` value. This return value is used in application termination ([Application termination](#)).

The entry point may optionally have one formal parameter. The parameter may have any name, but the type of the parameter must be `string[]`. If the formal parameter is present, the execution environment creates and passes a `string[]` argument containing the command-line arguments that were specified when the application was started. The `string[]` argument is never null, but it may have a length of zero if no command-line arguments were specified.

Since C# supports method overloading, a class or struct may contain multiple definitions of some method, provided each has a different signature. However, within a single program, no class or struct may contain more than one method called `Main` whose definition qualifies it to be used as an application entry point. Other overloaded versions of `Main` are permitted, however, provided they have more than one parameter, or their only parameter is other than type `string[]`.

An application can be made up of multiple classes or structs. It is possible for more than one of these classes or structs to contain a method called `Main` whose definition qualifies it to be used as an application entry point. In such cases, an external mechanism (such as a command-line compiler option) must be used to select one of these `Main` methods as the entry point.

In C#, every method must be defined as a member of a class or struct. Ordinarily, the declared accessibility ([Declared accessibility](#)) of a method is determined by the access modifiers ([Access modifiers](#)) specified in its declaration, and similarly the declared accessibility of a type is determined by the access modifiers specified in

its declaration. In order for a given method of a given type to be callable, both the type and the member must be accessible. However, the application entry point is a special case. Specifically, the execution environment can access the application's entry point regardless of its declared accessibility and regardless of the declared accessibility of its enclosing type declarations.

The application entry point method may not be in a generic class declaration.

In all other respects, entry point methods behave like those that are not entry points.

Application termination

Application termination returns control to the execution environment.

If the return type of the application's *entry point* method is `int`, the value returned serves as the application's *termination status code*. The purpose of this code is to allow communication of success or failure to the execution environment.

If the return type of the entry point method is `void`, reaching the right brace (`}`) which terminates that method, or executing a `return` statement that has no expression, results in a termination status code of `0`.

Prior to an application's termination, destructors for all of its objects that have not yet been garbage collected are called, unless such cleanup has been suppressed (by a call to the library method `GC.SuppressFinalize`, for example).

Declarations

Declarations in a C# program define the constituent elements of the program. C# programs are organized using namespaces ([Namespaces](#)), which can contain type declarations and nested namespace declarations. Type declarations ([Type declarations](#)) are used to define classes ([Classes](#)), structs ([Structs](#)), interfaces ([Interfaces](#)), enums ([Enums](#)), and delegates ([Delegates](#)). The kinds of members permitted in a type declaration depend on the form of the type declaration. For instance, class declarations can contain declarations for constants ([Constants](#)), fields ([Fields](#)), methods ([Methods](#)), properties ([Properties](#)), events ([Events](#)), indexers ([Indexers](#)), operators ([Operators](#)), instance constructors ([Instance constructors](#)), static constructors ([Static constructors](#)), destructors ([Destructors](#)), and nested types ([Nested types](#)).

A declaration defines a name in the *declaration space* to which the declaration belongs. Except for overloaded members ([Signatures and overloading](#)), it is a compile-time error to have two or more declarations that introduce members with the same name in a declaration space. It is never possible for a declaration space to contain different kinds of members with the same name. For example, a declaration space can never contain a field and a method by the same name.

There are several different types of declaration spaces, as described in the following.

- Within all source files of a program, *namespace_member_declarations* with no enclosing *namespace_declaration* are members of a single combined declaration space called the *global declaration space*.
- Within all source files of a program, *namespace_member_declarations* within *namespace_declarations* that have the same fully qualified namespace name are members of a single combined declaration space.
- Each class, struct, or interface declaration creates a new declaration space. Names are introduced into this declaration space through *class_member_declarations*, *struct_member_declarations*, *interface_member_declarations*, or *type_parameters*. Except for overloaded instance constructor declarations and static constructor declarations, a class or struct cannot contain a member declaration with the same name as the class or struct. A class, struct, or interface permits the declaration of overloaded methods and indexers. Furthermore, a class or struct permits the declaration of overloaded instance constructors and operators. For example, a class, struct, or interface may contain multiple method declarations with the same

name, provided these method declarations differ in their signature ([Signatures and overloading](#)). Note that base classes do not contribute to the declaration space of a class, and base interfaces do not contribute to the declaration space of an interface. Thus, a derived class or interface is allowed to declare a member with the same name as an inherited member. Such a member is said to *hide* the inherited member.

- Each delegate declaration creates a new declaration space. Names are introduced into this declaration space through formal parameters (*fixed_parameters* and *parameter_arrays*) and *type_parameters*.
- Each enumeration declaration creates a new declaration space. Names are introduced into this declaration space through *enum_member_declarations*.
- Each method declaration, indexer declaration, operator declaration, instance constructor declaration and anonymous function creates a new declaration space called a **local variable declaration space**. Names are introduced into this declaration space through formal parameters (*fixed_parameters* and *parameter_arrays*) and *type_parameters*. The body of the function member or anonymous function, if any, is considered to be nested within the local variable declaration space. It is an error for a local variable declaration space and a nested local variable declaration space to contain elements with the same name. Thus, within a nested declaration space it is not possible to declare a local variable or constant with the same name as a local variable or constant in an enclosing declaration space. It is possible for two declaration spaces to contain elements with the same name as long as neither declaration space contains the other.
- Each *block* or *switch_block*, as well as a *for*, *foreach* and *using* statement, creates a local variable declaration space for local variables and local constants. Names are introduced into this declaration space through *local_variable_declarations* and *local_constant_declarations*. Note that blocks that occur as or within the body of a function member or anonymous function are nested within the local variable declaration space declared by those functions for their parameters. Thus it is an error to have e.g. a method with a local variable and a parameter of the same name.
- Each *block* or *switch_block* creates a separate declaration space for labels. Names are introduced into this declaration space through *labeled_statements*, and the names are referenced through *goto_statements*. The **label declaration space** of a block includes any nested blocks. Thus, within a nested block it is not possible to declare a label with the same name as a label in an enclosing block.

The textual order in which names are declared is generally of no significance. In particular, textual order is not significant for the declaration and use of namespaces, constants, methods, properties, events, indexers, operators, instance constructors, destructors, static constructors, and types. Declaration order is significant in the following ways:

- Declaration order for field declarations and local variable declarations determines the order in which their initializers (if any) are executed.
- Local variables must be defined before they are used ([Scopes](#)).
- Declaration order for enum member declarations ([Enum members](#)) is significant when *constant_expression* values are omitted.

The declaration space of a namespace is "open ended", and two namespace declarations with the same fully qualified name contribute to the same declaration space. For example

```

namespace Megacorp.Data
{
    class Customer
    {
        ...
    }
}

namespace Megacorp.Data
{
    class Order
    {
        ...
    }
}

```

The two namespace declarations above contribute to the same declaration space, in this case declaring two classes with the fully qualified names `Megacorp.Data.Customer` and `Megacorp.Data.Order`. Because the two declarations contribute to the same declaration space, it would have caused a compile-time error if each contained a declaration of a class with the same name.

As specified above, the declaration space of a block includes any nested blocks. Thus, in the following example, the `F` and `G` methods result in a compile-time error because the name `i` is declared in the outer block and cannot be redeclared in the inner block. However, the `H` and `I` methods are valid since the two `i`'s are declared in separate non-nested blocks.

```

class A
{
    void F() {
        int i = 0;
        if (true) {
            int i = 1;
        }
    }

    void G() {
        if (true) {
            int i = 0;
        }
        int i = 1;
    }

    void H() {
        if (true) {
            int i = 0;
        }
        if (true) {
            int i = 1;
        }
    }

    void I() {
        for (int i = 0; i < 10; i++)
            H();
        for (int i = 0; i < 10; i++)
            H();
    }
}

```

Members

Namespaces and types have **members**. The members of an entity are generally available through the use of a qualified name that starts with a reference to the entity, followed by a "." token, followed by the name of the member.

Members of a type are either declared in the type declaration or **inherited** from the base class of the type. When a type inherits from a base class, all members of the base class, except instance constructors, destructors and static constructors, become members of the derived type. The declared accessibility of a base class member does not control whether the member is inherited—inheritance extends to any member that isn't an instance constructor, static constructor, or destructor. However, an inherited member may not be accessible in a derived type, either because of its declared accessibility ([Declared accessibility](#)) or because it is hidden by a declaration in the type itself ([Hiding through inheritance](#)).

Namespace members

Namespaces and types that have no enclosing namespace are members of the **global namespace**. This corresponds directly to the names declared in the global declaration space.

Namespaces and types declared within a namespace are members of that namespace. This corresponds directly to the names declared in the declaration space of the namespace.

Namespaces have no access restrictions. It is not possible to declare private, protected, or internal namespaces, and namespace names are always publicly accessible.

Struct members

The members of a struct are the members declared in the struct and the members inherited from the struct's direct base class `System.ValueType` and the indirect base class `object`.

The members of a simple type correspond directly to the members of the struct type aliased by the simple type:

- The members of `sbyte` are the members of the `System.SByte` struct.
- The members of `byte` are the members of the `System.Byte` struct.
- The members of `short` are the members of the `System.Int16` struct.
- The members of `ushort` are the members of the `System.UInt16` struct.
- The members of `int` are the members of the `System.Int32` struct.
- The members of `uint` are the members of the `System.UInt32` struct.
- The members of `long` are the members of the `System.Int64` struct.
- The members of `ulong` are the members of the `System.UInt64` struct.
- The members of `char` are the members of the `System.Char` struct.
- The members of `float` are the members of the `System.Single` struct.
- The members of `double` are the members of the `System.Double` struct.
- The members of `decimal` are the members of the `System.Decimal` struct.
- The members of `bool` are the members of the `System.Boolean` struct.

Enumeration members

The members of an enumeration are the constants declared in the enumeration and the members inherited from the enumeration's direct base class `System.Enum` and the indirect base classes `System.ValueType` and `object`.

Class members

The members of a class are the members declared in the class and the members inherited from the base class (except for class `object` which has no base class). The members inherited from the base class include the constants, fields, methods, properties, events, indexers, operators, and types of the base class, but not the instance constructors, destructors and static constructors of the base class. Base class members are inherited without regard to their accessibility.

A class declaration may contain declarations of constants, fields, methods, properties, events, indexers, operators, instance constructors, destructors, static constructors and types.

The members of `object` and `string` correspond directly to the members of the class types they alias:

- The members of `object` are the members of the `System.Object` class.
- The members of `string` are the members of the `System.String` class.

Interface members

The members of an interface are the members declared in the interface and in all base interfaces of the interface.

The members in class `object` are not, strictly speaking, members of any interface ([Interface members](#)).

However, the members in class `object` are available via member lookup in any interface type ([Member lookup](#)).

Array members

The members of an array are the members inherited from class `System.Array`.

Delegate members

The members of a delegate are the members inherited from class `System.Delegate`.

Member access

Declarations of members allow control over member access. The accessibility of a member is established by the declared accessibility ([Declared accessibility](#)) of the member combined with the accessibility of the immediately containing type, if any.

When access to a particular member is allowed, the member is said to be *accessible*. Conversely, when access to a particular member is disallowed, the member is said to be *inaccessible*. Access to a member is permitted when the textual location in which the access takes place is included in the accessibility domain ([Accessibility domains](#)) of the member.

Declared accessibility

The *declared accessibility* of a member can be one of the following:

- Public, which is selected by including a `public` modifier in the member declaration. The intuitive meaning of `public` is "access not limited".
- Protected, which is selected by including a `protected` modifier in the member declaration. The intuitive meaning of `protected` is "access limited to the containing class or types derived from the containing class".
- Internal, which is selected by including an `internal` modifier in the member declaration. The intuitive meaning of `internal` is "access limited to this program".
- Protected internal (meaning protected or internal), which is selected by including both a `protected` and an `internal` modifier in the member declaration. The intuitive meaning of `protected internal` is "access limited to this program or types derived from the containing class".
- Private, which is selected by including a `private` modifier in the member declaration. The intuitive meaning of `private` is "access limited to the containing type".

Depending on the context in which a member declaration takes place, only certain types of declared accessibility are permitted. Furthermore, when a member declaration does not include any access modifiers, the context in which the declaration takes place determines the default declared accessibility.

- Namespaces implicitly have `public` declared accessibility. No access modifiers are allowed on namespace declarations.
- Types declared in compilation units or namespaces can have `public` or `internal` declared accessibility and default to `internal` declared accessibility.
- Class members can have any of the five kinds of declared accessibility and default to `private` declared

accessibility. (Note that a type declared as a member of a class can have any of the five kinds of declared accessibility, whereas a type declared as a member of a namespace can have only `public` or `internal` declared accessibility.)

- Struct members can have `public`, `internal`, or `private` declared accessibility and default to `private` declared accessibility because structs are implicitly sealed. Struct members introduced in a struct (that is, not inherited by that struct) cannot have `protected` or `protected internal` declared accessibility. (Note that a type declared as a member of a struct can have `public`, `internal`, or `private` declared accessibility, whereas a type declared as a member of a namespace can have only `public` or `internal` declared accessibility.)
- Interface members implicitly have `public` declared accessibility. No access modifiers are allowed on interface member declarations.
- Enumeration members implicitly have `public` declared accessibility. No access modifiers are allowed on enumeration member declarations.

Accessibility domains

The **accessibility domain** of a member consists of the (possibly disjoint) sections of program text in which access to the member is permitted. For purposes of defining the accessibility domain of a member, a member is said to be **top-level** if it is not declared within a type, and a member is said to be **nested** if it is declared within another type. Furthermore, the **program text** of a program is defined as all program text contained in all source files of the program, and the program text of a type is defined as all program text contained in the *type_declarations* of that type (including, possibly, types that are nested within the type).

The accessibility domain of a predefined type (such as `object`, `int`, or `double`) is unlimited.

The accessibility domain of a top-level unbound type `T` ([Bound and unbound types](#)) that is declared in a program `P` is defined as follows:

- If the declared accessibility of `T` is `public`, the accessibility domain of `T` is the program text of `P` and any program that references `P`.
- If the declared accessibility of `T` is `internal`, the accessibility domain of `T` is the program text of `P`.

From these definitions it follows that the accessibility domain of a top-level unbound type is always at least the program text of the program in which that type is declared.

The accessibility domain for a constructed type `T<A1, ..., An>` is the intersection of the accessibility domain of the unbound generic type `T` and the accessibility domains of the type arguments `A1, ..., An`.

The accessibility domain of a nested member `M` declared in a type `T` within a program `P` is defined as follows (noting that `M` itself may possibly be a type):

- If the declared accessibility of `M` is `public`, the accessibility domain of `M` is the accessibility domain of `T`.
- If the declared accessibility of `M` is `protected internal`, let `D` be the union of the program text of `P` and the program text of any type derived from `T`, which is declared outside `P`. The accessibility domain of `M` is the intersection of the accessibility domain of `T` with `D`.
- If the declared accessibility of `M` is `protected`, let `D` be the union of the program text of `T` and the program text of any type derived from `T`. The accessibility domain of `M` is the intersection of the accessibility domain of `T` with `D`.
- If the declared accessibility of `M` is `internal`, the accessibility domain of `M` is the intersection of the accessibility domain of `T` with the program text of `P`.
- If the declared accessibility of `M` is `private`, the accessibility domain of `M` is the program text of `T`.

From these definitions it follows that the accessibility domain of a nested member is always at least the program text of the type in which the member is declared. Furthermore, it follows that the accessibility domain of a member is never more inclusive than the accessibility domain of the type in which the member is declared.

In intuitive terms, when a type or member `M` is accessed, the following steps are evaluated to ensure that the access is permitted:

- First, if `M` is declared within a type (as opposed to a compilation unit or a namespace), a compile-time error occurs if that type is not accessible.
- Then, if `M` is `public`, the access is permitted.
- Otherwise, if `M` is `protected internal`, the access is permitted if it occurs within the program in which `M` is declared, or if it occurs within a class derived from the class in which `M` is declared and takes place through the derived class type ([Protected access for instance members](#)).
- Otherwise, if `M` is `protected`, the access is permitted if it occurs within the class in which `M` is declared, or if it occurs within a class derived from the class in which `M` is declared and takes place through the derived class type ([Protected access for instance members](#)).
- Otherwise, if `M` is `internal`, the access is permitted if it occurs within the program in which `M` is declared.
- Otherwise, if `M` is `private`, the access is permitted if it occurs within the type in which `M` is declared.
- Otherwise, the type or member is inaccessible, and a compile-time error occurs.

In the example

```
public class A
{
    public static int X;
    internal static int Y;
    private static int Z;
}

internal class B
{
    public static int X;
    internal static int Y;
    private static int Z;

    public class C
    {
        public static int X;
        internal static int Y;
        private static int Z;
    }

    private class D
    {
        public static int X;
        internal static int Y;
        private static int Z;
    }
}
```

the classes and members have the following accessibility domains:

- The accessibility domain of `A` and `A.X` is unlimited.
- The accessibility domain of `A.Y`, `B`, `B.X`, `B.Y`, `B.C`, `B.C.X`, and `B.C.Y` is the program text of the containing program.
- The accessibility domain of `A.Z` is the program text of `A`.
- The accessibility domain of `B.Z` and `B.D` is the program text of `B`, including the program text of `B.C` and `B.D`.
- The accessibility domain of `B.C.Z` is the program text of `B.C`.
- The accessibility domain of `B.D.X` and `B.D.Y` is the program text of `B`, including the program text of `B.C`

and `B.D`.

- The accessibility domain of `B.D.Z` is the program text of `B.D`.

As the example illustrates, the accessibility domain of a member is never larger than that of a containing type. For example, even though all `X` members have public declared accessibility, all but `A.X` have accessibility domains that are constrained by a containing type.

As described in [Members](#), all members of a base class, except for instance constructors, destructors and static constructors, are inherited by derived types. This includes even private members of a base class. However, the accessibility domain of a private member includes only the program text of the type in which the member is declared. In the example

```
class A
{
    int x;

    static void F(B b) {
        b.x = 1;      // Ok
    }
}

class B: A
{
    static void F(B b) {
        b.x = 1;      // Error, x not accessible
    }
}
```

the `B` class inherits the private member `x` from the `A` class. Because the member is private, it is only accessible within the *class_body* of `A`. Thus, the access to `b.x` succeeds in the `A.F` method, but fails in the `B.F` method.

Protected access for instance members

When a `protected` instance member is accessed outside the program text of the class in which it is declared, and when a `protected internal` instance member is accessed outside the program text of the program in which it is declared, the access must take place within a class declaration that derives from the class in which it is declared. Furthermore, the access is required to take place through an instance of that derived class type or a class type constructed from it. This restriction prevents one derived class from accessing protected members of other derived classes, even when the members are inherited from the same base class.

Let `B` be a base class that declares a protected instance member `M`, and let `D` be a class that derives from `B`. Within the *class_body* of `D`, access to `M` can take one of the following forms:

- An unqualified *type_name* or *primary_expression* of the form `M`.
- A *primary_expression* of the form `E.M`, provided the type of `E` is `T` or a class derived from `T`, where `T` is the class type `D`, or a class type constructed from `D`.
- A *primary_expression* of the form `base.M`.

In addition to these forms of access, a derived class can access a protected instance constructor of a base class in a *constructor_initializer* ([Constructor initializers](#)).

In the example

```

public class A
{
    protected int x;

    static void F(A a, B b) {
        a.x = 1;        // Ok
        b.x = 1;        // Ok
    }
}

public class B: A
{
    static void F(A a, B b) {
        a.x = 1;        // Error, must access through instance of B
        b.x = 1;        // Ok
    }
}

```

within `A`, it is possible to access `x` through instances of both `A` and `B`, since in either case the access takes place through an instance of `A` or a class derived from `A`. However, within `B`, it is not possible to access `x` through an instance of `A`, since `A` does not derive from `B`.

In the example

```

class C<T>
{
    protected T x;
}

class D<T>: C<T>
{
    static void F() {
        D<T> dt = new D<T>();
        D<int> di = new D<int>();
        D<string> ds = new D<string>();
        dt.x = default(T);
        di.x = 123;
        ds.x = "test";
    }
}

```

the three assignments to `x` are permitted because they all take place through instances of class types constructed from the generic type.

Accessibility constraints

Several constructs in the C# language require a type to be *at least as accessible as* a member or another type. A type `T` is said to be at least as accessible as a member or type `M` if the accessibility domain of `T` is a superset of the accessibility domain of `M`. In other words, `T` is at least as accessible as `M` if `T` is accessible in all contexts in which `M` is accessible.

The following accessibility constraints exist:

- The direct base class of a class type must be at least as accessible as the class type itself.
- The explicit base interfaces of an interface type must be at least as accessible as the interface type itself.
- The return type and parameter types of a delegate type must be at least as accessible as the delegate type itself.
- The type of a constant must be at least as accessible as the constant itself.
- The type of a field must be at least as accessible as the field itself.
- The return type and parameter types of a method must be at least as accessible as the method itself.

- The type of a property must be at least as accessible as the property itself.
- The type of an event must be at least as accessible as the event itself.
- The type and parameter types of an indexer must be at least as accessible as the indexer itself.
- The return type and parameter types of an operator must be at least as accessible as the operator itself.
- The parameter types of an instance constructor must be at least as accessible as the instance constructor itself.

In the example

```
class A {...}

public class B: A {...}
```

the `B` class results in a compile-time error because `A` is not at least as accessible as `B`.

Likewise, in the example

```
class A {...}

public class B
{
    A F() {...}

    internal A G() {...}

    public A H() {...}
}
```

the `H` method in `B` results in a compile-time error because the return type `A` is not at least as accessible as the method.

Signatures and overloading

Methods, instance constructors, indexers, and operators are characterized by their *signatures*:

- The signature of a method consists of the name of the method, the number of type parameters and the type and kind (value, reference, or output) of each of its formal parameters, considered in the order left to right. For these purposes, any type parameter of the method that occurs in the type of a formal parameter is identified not by its name, but by its ordinal position in the type argument list of the method. The signature of a method specifically does not include the return type, the `params` modifier that may be specified for the right-most parameter, nor the optional type parameter constraints.
- The signature of an instance constructor consists of the type and kind (value, reference, or output) of each of its formal parameters, considered in the order left to right. The signature of an instance constructor specifically does not include the `params` modifier that may be specified for the right-most parameter.
- The signature of an indexer consists of the type of each of its formal parameters, considered in the order left to right. The signature of an indexer specifically does not include the element type, nor does it include the `params` modifier that may be specified for the right-most parameter.
- The signature of an operator consists of the name of the operator and the type of each of its formal parameters, considered in the order left to right. The signature of an operator specifically does not include the result type.

Signatures are the enabling mechanism for *overloading* of members in classes, structs, and interfaces:

- Overloading of methods permits a class, struct, or interface to declare multiple methods with the same name, provided their signatures are unique within that class, struct, or interface.

- Overloading of instance constructors permits a class or struct to declare multiple instance constructors, provided their signatures are unique within that class or struct.
- Overloading of indexers permits a class, struct, or interface to declare multiple indexers, provided their signatures are unique within that class, struct, or interface.
- Overloading of operators permits a class or struct to declare multiple operators with the same name, provided their signatures are unique within that class or struct.

Although `out` and `ref` parameter modifiers are considered part of a signature, members declared in a single type cannot differ in signature solely by `ref` and `out`. A compile-time error occurs if two members are declared in the same type with signatures that would be the same if all parameters in both methods with `out` modifiers were changed to `ref` modifiers. For other purposes of signature matching (e.g., hiding or overriding), `ref` and `out` are considered part of the signature and do not match each other. (This restriction is to allow C# programs to be easily translated to run on the Common Language Infrastructure (CLI), which does not provide a way to define methods that differ solely in `ref` and `out`.)

For the purposes of signatures, the types `object` and `dynamic` are considered the same. Members declared in a single type can therefore not differ in signature solely by `object` and `dynamic`.

The following example shows a set of overloaded method declarations along with their signatures.

```
interface ITest
{
    void F();                // F()

    void F(int x);           // F(int)

    void F(ref int x);        // F(ref int)

    void F(out int x);        // F(out int)    error

    void F(int x, int y);     // F(int, int)

    int F(string s);         // F(string)

    int F(int x);            // F(int)        error

    void F(string[] a);       // F(string[])

    void F(params string[] a); // F(string[])    error
}
```

Note that any `ref` and `out` parameter modifiers ([Method parameters](#)) are part of a signature. Thus, `F(int)` and `F(ref int)` are unique signatures. However, `F(ref int)` and `F(out int)` cannot be declared within the same interface because their signatures differ solely by `ref` and `out`. Also, note that the return type and the `params` modifier are not part of a signature, so it is not possible to overload solely based on return type or on the inclusion or exclusion of the `params` modifier. As such, the declarations of the methods `F(int)` and `F(params string[])` identified above result in a compile-time error.

Scopes

The *scope* of a name is the region of program text within which it is possible to refer to the entity declared by the name without qualification of the name. Scopes can be *nested*, and an inner scope may redeclare the meaning of a name from an outer scope (this does not, however, remove the restriction imposed by [Declarations](#) that within a nested block it is not possible to declare a local variable with the same name as a local variable in an enclosing block). The name from the outer scope is then said to be *hidden* in the region of program text covered by the inner scope, and access to the outer name is only possible by qualifying the name.

- The scope of a namespace member declared by a *namespace_member_declaration* ([Namespace members](#)) with no enclosing *namespace_declaration* is the entire program text.
- The scope of a namespace member declared by a *namespace_member_declaration* within a *namespace_declaration* whose fully qualified name is `N` is the *namespace_body* of every *namespace_declaration* whose fully qualified name is `N` or starts with `N`, followed by a period.
- The scope of name defined by an *extern_alias_directive* extends over the *using_directives*, *global_attributes* and *namespace_member_declarations* of its immediately containing compilation unit or namespace body. An *extern_alias_directive* does not contribute any new members to the underlying declaration space. In other words, an *extern_alias_directive* is not transitive, but, rather, affects only the compilation unit or namespace body in which it occurs.
- The scope of a name defined or imported by a *using_directive* ([Using directives](#)) extends over the *namespace_member_declarations* of the *compilation_unit* or *namespace_body* in which the *using_directive* occurs. A *using_directive* may make zero or more namespace, type or member names available within a particular *compilation_unit* or *namespace_body*, but does not contribute any new members to the underlying declaration space. In other words, a *using_directive* is not transitive but rather affects only the *compilation_unit* or *namespace_body* in which it occurs.
- The scope of a type parameter declared by a *type_parameter_list* on a *class_declaration* ([Class declarations](#)) is the *class_base*, *type_parameter_constraints_clauses*, and *class_body* of that *class_declaration*.
- The scope of a type parameter declared by a *type_parameter_list* on a *struct_declaration* ([Struct declarations](#)) is the *struct_interfaces*, *type_parameter_constraints_clauses*, and *struct_body* of that *struct_declaration*.
- The scope of a type parameter declared by a *type_parameter_list* on an *interface_declaration* ([Interface declarations](#)) is the *interface_base*, *type_parameter_constraints_clauses*, and *interface_body* of that *interface_declaration*.
- The scope of a type parameter declared by a *type_parameter_list* on a *delegate_declaration* ([Delegate declarations](#)) is the *return_type*, *formal_parameter_list*, and *type_parameter_constraints_clauses* of that *delegate_declaration*.
- The scope of a member declared by a *class_member_declaration* ([Class body](#)) is the *class_body* in which the declaration occurs. In addition, the scope of a class member extends to the *class_body* of those derived classes that are included in the accessibility domain ([Accessibility domains](#)) of the member.
- The scope of a member declared by a *struct_member_declaration* ([Struct members](#)) is the *struct_body* in which the declaration occurs.
- The scope of a member declared by an *enum_member_declaration* ([Enum members](#)) is the *enum_body* in which the declaration occurs.
- The scope of a parameter declared in a *method_declaration* ([Methods](#)) is the *method_body* of that *method_declaration*.
- The scope of a parameter declared in an *indexer_declaration* ([Indexers](#)) is the *accessor_declarations* of that *indexer_declaration*.
- The scope of a parameter declared in an *operator_declaration* ([Operators](#)) is the *block* of that *operator_declaration*.
- The scope of a parameter declared in a *constructor_declaration* ([Instance constructors](#)) is the *constructor_initializer* and *block* of that *constructor_declaration*.
- The scope of a parameter declared in a *lambda_expression* ([Anonymous function expressions](#)) is the *anonymous_function_body* of that *lambda_expression*.
- The scope of a parameter declared in an *anonymous_method_expression* ([Anonymous function expressions](#)) is the *block* of that *anonymous_method_expression*.
- The scope of a label declared in a *labeled_statement* ([Labeled statements](#)) is the *block* in which the declaration occurs.
- The scope of a local variable declared in a *local_variable_declaration* ([Local variable declarations](#)) is the block in which the declaration occurs.

- The scope of a local variable declared in a *switch_block* of a `switch` statement ([The switch statement](#)) is the *switch_block*.
- The scope of a local variable declared in a *for_initializer* of a `for` statement ([The for statement](#)) is the *for_initializer*, the *for_condition*, the *for_iterator*, and the contained *statement* of the `for` statement.
- The scope of a local constant declared in a *local_constant_declaration* ([Local constant declarations](#)) is the block in which the declaration occurs. It is a compile-time error to refer to a local constant in a textual position that precedes its *constant_declarator*.
- The scope of a variable declared as part of a *foreach_statement*, *using_statement*, *lock_statement* or *query_expression* is determined by the expansion of the given construct.

Within the scope of a namespace, class, struct, or enumeration member it is possible to refer to the member in a textual position that precedes the declaration of the member. For example

```
class A
{
    void F() {
        i = 1;
    }

    int i = 0;
}
```

Here, it is valid for `F` to refer to `i` before it is declared.

Within the scope of a local variable, it is a compile-time error to refer to the local variable in a textual position that precedes the *local_variable_declarator* of the local variable. For example

```
class A
{
    int i = 0;

    void F() {
        i = 1;           // Error, use precedes declaration
        int i;
        i = 2;
    }

    void G() {
        int j = (j = 1); // Valid
    }

    void H() {
        int a = 1, b = ++a; // Valid
    }
}
```

In the `F` method above, the first assignment to `i` specifically does not refer to the field declared in the outer scope. Rather, it refers to the local variable and it results in a compile-time error because it textually precedes the declaration of the variable. In the `G` method, the use of `j` in the initializer for the declaration of `j` is valid because the use does not precede the *local_variable_declarator*. In the `H` method, a subsequent *local_variable_declarator* correctly refers to a local variable declared in an earlier *local_variable_declarator* within the same *local_variable_declaration*.

The scoping rules for local variables are designed to guarantee that the meaning of a name used in an expression context is always the same within a block. If the scope of a local variable were to extend only from its declaration to the end of the block, then in the example above, the first assignment would assign to the instance variable and the second assignment would assign to the local variable, possibly leading to compile-time errors if

the statements of the block were later to be rearranged.

The meaning of a name within a block may differ based on the context in which the name is used. In the example

```
using System;

class A {}

class Test
{
    static void Main() {
        string A = "hello, world";
        string s = A;                                // expression context

        Type t = typeof(A);                          // type context

        Console.WriteLine(s);                        // writes "hello, world"
        Console.WriteLine(t);                        // writes "A"
    }
}
```

the name `A` is used in an expression context to refer to the local variable `A` and in a type context to refer to the class `A`.

Name hiding

The scope of an entity typically encompasses more program text than the declaration space of the entity. In particular, the scope of an entity may include declarations that introduce new declaration spaces containing entities of the same name. Such declarations cause the original entity to become *hidden*. Conversely, an entity is said to be *visible* when it is not hidden.

Name hiding occurs when scopes overlap through nesting and when scopes overlap through inheritance. The characteristics of the two types of hiding are described in the following sections.

Hiding through nesting

Name hiding through nesting can occur as a result of nesting namespaces or types within namespaces, as a result of nesting types within classes or structs, and as a result of parameter and local variable declarations.

In the example

```
class A
{
    int i = 0;

    void F() {
        int i = 1;
    }

    void G() {
        i = 1;
    }
}
```

within the `F` method, the instance variable `i` is hidden by the local variable `i`, but within the `G` method, `i` still refers to the instance variable.

When a name in an inner scope hides a name in an outer scope, it hides all overloaded occurrences of that name. In the example

```

class Outer
{
    static void F(int i) {}

    static void F(string s) {}

    class Inner
    {
        void G() {
            F(1);           // Invokes Outer.Inner.F
            F("Hello");      // Error
        }

        static void F(long l) {}
    }
}

```

the call `F(1)` invokes the `F` declared in `Inner` because all outer occurrences of `F` are hidden by the inner declaration. For the same reason, the call `F("Hello")` results in a compile-time error.

Hiding through inheritance

Name hiding through inheritance occurs when classes or structs redeclare names that were inherited from base classes. This type of name hiding takes one of the following forms:

- A constant, field, property, event, or type introduced in a class or struct hides all base class members with the same name.
- A method introduced in a class or struct hides all non-method base class members with the same name, and all base class methods with the same signature (method name and parameter count, modifiers, and types).
- An indexer introduced in a class or struct hides all base class indexers with the same signature (parameter count and types).

The rules governing operator declarations ([Operators](#)) make it impossible for a derived class to declare an operator with the same signature as an operator in a base class. Thus, operators never hide one another.

Contrary to hiding a name from an outer scope, hiding an accessible name from an inherited scope causes a warning to be reported. In the example

```

class Base
{
    public void F() {}
}

class Derived: Base
{
    public void F() {}           // Warning, hiding an inherited name
}

```

the declaration of `F` in `Derived` causes a warning to be reported. Hiding an inherited name is specifically not an error, since that would preclude separate evolution of base classes. For example, the above situation might have come about because a later version of `Base` introduced an `F` method that wasn't present in an earlier version of the class. Had the above situation been an error, then any change made to a base class in a separately versioned class library could potentially cause derived classes to become invalid.

The warning caused by hiding an inherited name can be eliminated through use of the `new` modifier:

```

class Base
{
    public void F() {}
}

class Derived: Base
{
    new public void F() {}
}

```

The `new` modifier indicates that the `F` in `Derived` is "new", and that it is indeed intended to hide the inherited member.

A declaration of a new member hides an inherited member only within the scope of the new member.

```

class Base
{
    public static void F() {}
}

class Derived: Base
{
    new private static void F() {}    // Hides Base.F in Derived only
}

class MoreDerived: Derived
{
    static void G() { F(); }          // Invokes Base.F
}

```

In the example above, the declaration of `F` in `Derived` hides the `F` that was inherited from `Base`, but since the new `F` in `Derived` has private access, its scope does not extend to `MoreDerived`. Thus, the call `F()` in `MoreDerived.G` is valid and will invoke `Base.F`.

Namespace and type names

Several contexts in a C# program require a *namespace_name* or a *type_name* to be specified.

```

namespace_name
    : namespace_or_type_name
    ;

type_name
    : namespace_or_type_name
    ;

namespace_or_type_name
    : identifier type_argument_list?
    | namespace_or_type_name '.' identifier type_argument_list?
    | qualified_alias_member
    ;

```

A *namespace_name* is a *namespace_or_type_name* that refers to a namespace. Following resolution as described below, the *namespace_or_type_name* of a *namespace_name* must refer to a namespace, or otherwise a compile-time error occurs. No type arguments ([Type arguments](#)) can be present in a *namespace_name* (only types can have type arguments).

A *type_name* is a *namespace_or_type_name* that refers to a type. Following resolution as described below, the *namespace_or_type_name* of a *type_name* must refer to a type, or otherwise a compile-time error occurs.

If the *namespace_or_type_name* is a qualified-alias-member its meaning is as described in [Namespace alias qualifiers](#). Otherwise, a *namespace_or_type_name* has one of four forms:

- `I`
- `I<A1, ..., Ak>`
- `N.I`
- `N.I<A1, ..., Ak>`

where `I` is a single identifier, `N` is a *namespace_or_type_name* and `<A1, ..., Ak>` is an optional *type_argument_list*. When no *type_argument_list* is specified, consider `k` to be zero.

The meaning of a *namespace_or_type_name* is determined as follows:

- If the *namespace_or_type_name* is of the form `I` or of the form `I<A1, ..., Ak>`:
 - If `k` is zero and the *namespace_or_type_name* appears within a generic method declaration ([Methods](#)) and if that declaration includes a type parameter ([Type parameters](#)) with name `I`, then the *namespace_or_type_name* refers to that type parameter.
 - Otherwise, if the *namespace_or_type_name* appears within a type declaration, then for each instance type `T` ([The instance type](#)), starting with the instance type of that type declaration and continuing with the instance type of each enclosing class or struct declaration (if any):
 - If `k` is zero and the declaration of `T` includes a type parameter with name `I`, then the *namespace_or_type_name* refers to that type parameter.
 - Otherwise, if the *namespace_or_type_name* appears within the body of the type declaration, and `T` or any of its base types contain a nested accessible type having name `I` and `k` type parameters, then the *namespace_or_type_name* refers to that type constructed with the given type arguments. If there is more than one such type, the type declared within the more derived type is selected. Note that non-type members (constants, fields, methods, properties, indexers, operators, instance constructors, destructors, and static constructors) and type members with a different number of type parameters are ignored when determining the meaning of the *namespace_or_type_name*.
 - If the previous steps were unsuccessful then, for each namespace `N`, starting with the namespace in which the *namespace_or_type_name* occurs, continuing with each enclosing namespace (if any), and ending with the global namespace, the following steps are evaluated until an entity is located:
 - If `k` is zero and `I` is the name of a namespace in `N`, then:
 - If the location where the *namespace_or_type_name* occurs is enclosed by a namespace declaration for `N` and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name `I` with a namespace or type, then the *namespace_or_type_name* is ambiguous and a compile-time error occurs.
 - Otherwise, the *namespace_or_type_name* refers to the namespace named `I` in `N`.
 - Otherwise, if `N` contains an accessible type having name `I` and `k` type parameters, then:
 - If `k` is zero and the location where the *namespace_or_type_name* occurs is enclosed by a namespace declaration for `N` and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name `I` with a namespace or type, then the *namespace_or_type_name* is ambiguous and a compile-time error occurs.
 - Otherwise, the *namespace_or_type_name* refers to the type constructed with the given type arguments.
 - Otherwise, if the location where the *namespace_or_type_name* occurs is enclosed by a namespace declaration for `N`:
 - If `k` is zero and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name `I` with an imported namespace or type,

then the *namespace_or_type_name* refers to that namespace or type.

- Otherwise, if the namespaces and type declarations imported by the *using_namespace_directives* and *using_alias_directives* of the namespace declaration contain exactly one accessible type having name `I` and `K` type parameters, then the *namespace_or_type_name* refers to that type constructed with the given type arguments.
- Otherwise, if the namespaces and type declarations imported by the *using_namespace_directives* and *using_alias_directives* of the namespace declaration contain more than one accessible type having name `I` and `K` type parameters, then the *namespace_or_type_name* is ambiguous and an error occurs.
- Otherwise, the *namespace_or_type_name* is undefined and a compile-time error occurs.
- Otherwise, the *namespace_or_type_name* is of the form `N.I` or of the form `N.I<A1, ..., Ak>`. `N` is first resolved as a *namespace_or_type_name*. If the resolution of `N` is not successful, a compile-time error occurs. Otherwise, `N.I` or `N.I<A1, ..., Ak>` is resolved as follows:
 - If `K` is zero and `N` refers to a namespace and `N` contains a nested namespace with name `I`, then the *namespace_or_type_name* refers to that nested namespace.
 - Otherwise, if `N` refers to a namespace and `N` contains an accessible type having name `I` and `K` type parameters, then the *namespace_or_type_name* refers to that type constructed with the given type arguments.
 - Otherwise, if `N` refers to a (possibly constructed) class or struct type and `N` or any of its base classes contain a nested accessible type having name `I` and `K` type parameters, then the *namespace_or_type_name* refers to that type constructed with the given type arguments. If there is more than one such type, the type declared within the more derived type is selected. Note that if the meaning of `N.I` is being determined as part of resolving the base class specification of `N` then the direct base class of `N` is considered to be object ([Base classes](#)).
 - Otherwise, `N.I` is an invalid *namespace_or_type_name*, and a compile-time error occurs.

A *namespace_or_type_name* is permitted to reference a static class ([Static classes](#)) only if

- The *namespace_or_type_name* is the `T` in a *namespace_or_type_name* of the form `T.I`, or
- The *namespace_or_type_name* is the `T` in a *typeof_expression* ([Argument lists1](#)) of the form `typeof(T)`.

Fully qualified names

Every namespace and type has a **fully qualified name**, which uniquely identifies the namespace or type amongst all others. The fully qualified name of a namespace or type `N` is determined as follows:

- If `N` is a member of the global namespace, its fully qualified name is `N`.
- Otherwise, its fully qualified name is `S.N`, where `S` is the fully qualified name of the namespace or type in which `N` is declared.

In other words, the fully qualified name of `N` is the complete hierarchical path of identifiers that lead to `N`, starting from the global namespace. Because every member of a namespace or type must have a unique name, it follows that the fully qualified name of a namespace or type is always unique.

The example below shows several namespace and type declarations along with their associated fully qualified names.

```

class A {}           // A

namespace X          // X
{
    class B          // X.B
    {
        class C {}   // X.B.C
    }

    namespace Y       // X.Y
    {
        class D {}   // X.Y.D
    }
}

namespace X.Y         // X.Y
{
    class E {}        // X.Y.E
}

```

Automatic memory management

C# employs automatic memory management, which frees developers from manually allocating and freeing the memory occupied by objects. Automatic memory management policies are implemented by a *garbage collector*. The memory management life cycle of an object is as follows:

1. When the object is created, memory is allocated for it, the constructor is run, and the object is considered live.
2. If the object, or any part of it, cannot be accessed by any possible continuation of execution, other than the running of destructors, the object is considered no longer in use, and it becomes eligible for destruction. The C# compiler and the garbage collector may choose to analyze code to determine which references to an object may be used in the future. For instance, if a local variable that is in scope is the only existing reference to an object, but that local variable is never referred to in any possible continuation of execution from the current execution point in the procedure, the garbage collector may (but is not required to) treat the object as no longer in use.
3. Once the object is eligible for destruction, at some unspecified later time the destructor ([Destructors](#)) (if any) for the object is run. Under normal circumstances the destructor for the object is run once only, though implementation-specific APIs may allow this behavior to be overridden.
4. Once the destructor for an object is run, if that object, or any part of it, cannot be accessed by any possible continuation of execution, including the running of destructors, the object is considered inaccessible and the object becomes eligible for collection.
5. Finally, at some time after the object becomes eligible for collection, the garbage collector frees the memory associated with that object.

The garbage collector maintains information about object usage, and uses this information to make memory management decisions, such as where in memory to locate a newly created object, when to relocate an object, and when an object is no longer in use or inaccessible.

Like other languages that assume the existence of a garbage collector, C# is designed so that the garbage collector may implement a wide range of memory management policies. For instance, C# does not require that destructors be run or that objects be collected as soon as they are eligible, or that destructors be run in any particular order, or on any particular thread.

The behavior of the garbage collector can be controlled, to some degree, via static methods on the class `System.GC`. This class can be used to request a collection to occur, destructors to be run (or not run), and so forth.

Since the garbage collector is allowed wide latitude in deciding when to collect objects and run destructors, a conforming implementation may produce output that differs from that shown by the following code. The program

```
using System;

class A
{
    ~A() {
        Console.WriteLine("Destruct instance of A");
    }
}

class B
{
    object Ref;

    public B(object o) {
        Ref = o;
    }

    ~B() {
        Console.WriteLine("Destruct instance of B");
    }
}

class Test
{
    static void Main() {
        B b = new B(new A());
        b = null;
        GC.Collect();
        GC.WaitForPendingFinalizers();
    }
}
```

creates an instance of class `A` and an instance of class `B`. These objects become eligible for garbage collection when the variable `b` is assigned the value `null`, since after this time it is impossible for any user-written code to access them. The output could be either

```
Destruct instance of A
Destruct instance of B
```

or

```
Destruct instance of B
Destruct instance of A
```

because the language imposes no constraints on the order in which objects are garbage collected.

In subtle cases, the distinction between "eligible for destruction" and "eligible for collection" can be important. For example,

```

using System;

class A
{
    ~A() {
        Console.WriteLine("Destruct instance of A");
    }

    public void F() {
        Console.WriteLine("A.F");
        Test.RefA = this;
    }
}

class B
{
    public A Ref;

    ~B() {
        Console.WriteLine("Destruct instance of B");
        Ref.F();
    }
}

class Test
{
    public static A RefA;
    public static B RefB;

    static void Main() {
        RefB = new B();
        RefA = new A();
        RefB.Ref = RefA;
        RefB = null;
        RefA = null;

        // A and B now eligible for destruction
        GC.Collect();
        GC.WaitForPendingFinalizers();

        // B now eligible for collection, but A is not
        if (RefA != null)
            Console.WriteLine("RefA is not null");
    }
}

```

In the above program, if the garbage collector chooses to run the destructor of `A` before the destructor of `B`, then the output of this program might be:

```

Destruct instance of A
Destruct instance of B
A.F
RefA is not null

```

Note that although the instance of `A` was not in use and `A`'s destructor was run, it is still possible for methods of `A` (in this case, `F`) to be called from another destructor. Also, note that running of a destructor may cause an object to become usable from the mainline program again. In this case, the running of `B`'s destructor caused an instance of `A` that was previously not in use to become accessible from the live reference `Test.RefA`. After the call to `WaitForPendingFinalizers`, the instance of `B` is eligible for collection, but the instance of `A` is not, because of the reference `Test.RefA`.

To avoid confusion and unexpected behavior, it is generally a good idea for destructors to only perform cleanup

on data stored in their object's own fields, and not to perform any actions on referenced objects or static fields.

An alternative to using destructors is to let a class implement the `System.IDisposable` interface. This allows the client of the object to determine when to release the resources of the object, typically by accessing the object as a resource in a `using` statement ([The using statement](#)).

Execution order

Execution of a C# program proceeds such that the side effects of each executing thread are preserved at critical execution points. A *side effect* is defined as a read or write of a volatile field, a write to a non-volatile variable, a write to an external resource, and the throwing of an exception. The critical execution points at which the order of these side effects must be preserved are references to volatile fields ([Volatile fields](#)), `lock` statements ([The lock statement](#)), and thread creation and termination. The execution environment is free to change the order of execution of a C# program, subject to the following constraints:

- Data dependence is preserved within a thread of execution. That is, the value of each variable is computed as if all statements in the thread were executed in original program order.
- Initialization ordering rules are preserved ([Field initialization](#) and [Variable initializers](#)).
- The ordering of side effects is preserved with respect to volatile reads and writes ([Volatile fields](#)). Additionally, the execution environment need not evaluate part of an expression if it can deduce that that expression's value is not used and that no needed side effects are produced (including any caused by calling a method or accessing a volatile field). When program execution is interrupted by an asynchronous event (such as an exception thrown by another thread), it is not guaranteed that the observable side effects are visible in the original program order.

Types

12/28/2021 • 33 minutes to read • [Edit Online](#)

The types of the C# language are divided into two main categories: *value types* and *reference types*. Both value types and reference types may be *generic types*, which take one or more *type parameters*. Type parameters can designate both value types and reference types.

```
type
    : value_type
    | reference_type
    | type_parameter
    | type_unsafe
    ;
```

The final category of types, pointers, is available only in unsafe code. This is discussed further in [Pointer types](#).

Value types differ from reference types in that variables of the value types directly contain their data, whereas variables of the reference types store *references* to their data, the latter being known as *objects*. With reference types, it is possible for two variables to reference the same object, and thus possible for operations on one variable to affect the object referenced by the other variable. With value types, the variables each have their own copy of the data, and it is not possible for operations on one to affect the other.

C#'s type system is unified such that a value of any type can be treated as an object. Every type in C# directly or indirectly derives from the `object` class type, and `object` is the ultimate base class of all types. Values of reference types are treated as objects simply by viewing the values as type `object`. Values of value types are treated as objects by performing boxing and unboxing operations ([Boxing and unboxing](#)).

Value types

A value type is either a struct type or an enumeration type. C# provides a set of predefined struct types called the *simple types*. The simple types are identified through reserved words.

```

value_type
    : struct_type
    | enum_type
    ;

struct_type
    : type_name
    | simple_type
    | nullable_type
    ;

simple_type
    : numeric_type
    | 'bool'
    ;

numeric_type
    : integral_type
    | floating_point_type
    | 'decimal'
    ;

integral_type
    : 'sbyte'
    | 'byte'
    | 'short'
    | 'ushort'
    | 'int'
    | 'uint'
    | 'long'
    | 'ulong'
    | 'char'
    ;

floating_point_type
    : 'float'
    | 'double'
    ;

nullable_type
    : non_nullable_value_type '?'
    ;

non_nullable_value_type
    : type
    ;

enum_type
    : type_name
    ;

```

Unlike a variable of a reference type, a variable of a value type can contain the value `null` only if the value type is a nullable type. For every non-nullable value type there is a corresponding nullable value type denoting the same set of values plus the value `null`.

Assignment to a variable of a value type creates a copy of the value being assigned. This differs from assignment to a variable of a reference type, which copies the reference but not the object identified by the reference.

The `System.ValueType` type

All value types implicitly inherit from the class `System.ValueType`, which, in turn, inherits from class `object`. It is not possible for any type to derive from a value type, and value types are thus implicitly sealed ([Sealed classes](#)).

Note that `System.ValueType` is not itself a *value_type*. Rather, it is a *class_type* from which all *value_types* are

automatically derived.

Default constructors

All value types implicitly declare a public parameterless instance constructor called the **default constructor**. The default constructor returns a zero-initialized instance known as the **default value** for the value type:

- For all *simple types*, the default value is the value produced by a bit pattern of all zeros:
 - For `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, and `ulong`, the default value is `0`.
 - For `char`, the default value is `'\x0000'`.
 - For `float`, the default value is `0.0f`.
 - For `double`, the default value is `0.0d`.
 - For `decimal`, the default value is `0.0m`.
 - For `bool`, the default value is `false`.
- For an *enum type* `E`, the default value is `0`, converted to the type `E`.
- For a *struct type*, the default value is the value produced by setting all value type fields to their default value and all reference type fields to `null`.
- For a *nullable type* the default value is an instance for which the `HasValue` property is false and the `Value` property is undefined. The default value is also known as the **null value** of the nullable type.

Like any other instance constructor, the default constructor of a value type is invoked using the `new` operator. For efficiency reasons, this requirement is not intended to actually have the implementation generate a constructor call. In the example below, variables `i` and `j` are both initialized to zero.

```
class A
{
    void F() {
        int i = 0;
        int j = new int();
    }
}
```

Because every value type implicitly has a public parameterless instance constructor, it is not possible for a struct type to contain an explicit declaration of a parameterless constructor. A struct type is however permitted to declare parameterized instance constructors ([Constructors](#)).

Struct types

A struct type is a value type that can declare constants, fields, methods, properties, indexers, operators, instance constructors, static constructors, and nested types. The declaration of struct types is described in [Struct declarations](#).

Simple types

C# provides a set of predefined struct types called the **simple types**. The simple types are identified through reserved words, but these reserved words are simply aliases for predefined struct types in the `System` namespace, as described in the table below.

RESERVED WORD	ALIASED TYPE
<code>sbyte</code>	<code>System.SByte</code>
<code>byte</code>	<code>System.Byte</code>
<code>short</code>	<code>System.Int16</code>

RESERVED WORD	ALIASED TYPE
<code>ushort</code>	<code>System.UInt16</code>
<code>int</code>	<code>System.Int32</code>
<code>uint</code>	<code>System.UInt32</code>
<code>long</code>	<code>System.Int64</code>
<code>ulong</code>	<code>System.UInt64</code>
<code>char</code>	<code>System.Char</code>
<code>float</code>	<code>System.Single</code>
<code>double</code>	<code>System.Double</code>
<code>bool</code>	<code>System.Boolean</code>
<code>decimal</code>	<code>System.Decimal</code>

Because a simple type aliases a struct type, every simple type has members. For example, `int` has the members declared in `System.Int32` and the members inherited from `System.Object`, and the following statements are permitted:

```
int i = int.MaxValue;           // System.Int32.MaxValue constant
string s = i.ToString();       // System.Int32.ToString() instance method
string t = 123.ToString();     // System.Int32.ToString() instance method
```

The simple types differ from other struct types in that they permit certain additional operations:

- Most simple types permit values to be created by writing *literals* ([Literals](#)). For example, `123` is a literal of type `int` and `'a'` is a literal of type `char`. C# makes no provision for literals of struct types in general, and non-default values of other struct types are ultimately always created through instance constructors of those struct types.
- When the operands of an expression are all simple type constants, it is possible for the compiler to evaluate the expression at compile-time. Such an expression is known as a *constant expression* ([Constant expressions](#)). Expressions involving operators defined by other struct types are not considered to be constant expressions.
- Through `const` declarations it is possible to declare constants of the simple types ([Constants](#)). It is not possible to have constants of other struct types, but a similar effect is provided by `static readonly` fields.
- Conversions involving simple types can participate in evaluation of conversion operators defined by other struct types, but a user-defined conversion operator can never participate in evaluation of another user-defined operator ([Evaluation of user-defined conversions](#)).

Integral types

C# supports nine integral types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, and `char`. The integral types have the following sizes and ranges of values:

- The `sbyte` type represents signed 8-bit integers with values between -128 and 127.
- The `byte` type represents unsigned 8-bit integers with values between 0 and 255.

- The `short` type represents signed 16-bit integers with values between -32768 and 32767.
- The `ushort` type represents unsigned 16-bit integers with values between 0 and 65535.
- The `int` type represents signed 32-bit integers with values between -2147483648 and 2147483647.
- The `uint` type represents unsigned 32-bit integers with values between 0 and 4294967295.
- The `long` type represents signed 64-bit integers with values between -9223372036854775808 and 9223372036854775807.
- The `ulong` type represents unsigned 64-bit integers with values between 0 and 18446744073709551615.
- The `char` type represents unsigned 16-bit integers with values between 0 and 65535. The set of possible values for the `char` type corresponds to the Unicode character set. Although `char` has the same representation as `ushort`, not all operations permitted on one type are permitted on the other.

The integral-type unary and binary operators always operate with signed 32-bit precision, unsigned 32-bit precision, signed 64-bit precision, or unsigned 64-bit precision:

- For the unary `+` and `~` operators, the operand is converted to type `T`, where `T` is the first of `int`, `uint`, `long`, and `ulong` that can fully represent all possible values of the operand. The operation is then performed using the precision of type `T`, and the type of the result is `T`.
- For the unary `-` operator, the operand is converted to type `T`, where `T` is the first of `int` and `long` that can fully represent all possible values of the operand. The operation is then performed using the precision of type `T`, and the type of the result is `T`. The unary `-` operator cannot be applied to operands of type `ulong`.
- For the binary `+`, `-`, `*`, `/`, `%`, `&`, `^`, `|`, `==`, `!=`, `>`, `<`, `>=`, and `<=` operators, the operands are converted to type `T`, where `T` is the first of `int`, `uint`, `long`, and `ulong` that can fully represent all possible values of both operands. The operation is then performed using the precision of type `T`, and the type of the result is `T` (or `bool` for the relational operators). It is not permitted for one operand to be of type `long` and the other to be of type `ulong` with the binary operators.
- For the binary `<<` and `>>` operators, the left operand is converted to type `T`, where `T` is the first of `int`, `uint`, `long`, and `ulong` that can fully represent all possible values of the operand. The operation is then performed using the precision of type `T`, and the type of the result is `T`.

The `char` type is classified as an integral type, but it differs from the other integral types in two ways:

- There are no implicit conversions from other types to the `char` type. In particular, even though the `sbyte`, `byte`, and `ushort` types have ranges of values that are fully representable using the `char` type, implicit conversions from `sbyte`, `byte`, or `ushort` to `char` do not exist.
- Constants of the `char` type must be written as *character literals* or as *integer literals* in combination with a cast to type `char`. For example, `(char)10` is the same as `'\x000A'`.

The `checked` and `unchecked` operators and statements are used to control overflow checking for integral-type arithmetic operations and conversions ([The checked and unchecked operators](#)). In a `checked` context, an overflow produces a compile-time error or causes a `System.OverflowException` to be thrown. In an `unchecked` context, overflows are ignored and any high-order bits that do not fit in the destination type are discarded.

Floating point types

C# supports two floating point types: `float` and `double`. The `float` and `double` types are represented using the 32-bit single-precision and 64-bit double-precision IEEE 754 formats, which provide the following sets of values:

- Positive zero and negative zero. In most situations, positive zero and negative zero behave identically as the simple value zero, but certain operations distinguish between the two ([Division operator](#)).
- Positive infinity and negative infinity. Infinities are produced by such operations as dividing a non-zero number by zero. For example, `1.0 / 0.0` yields positive infinity, and `-1.0 / 0.0` yields negative infinity.

- The **Not-a-Number** value, often abbreviated NaN. NaNs are produced by invalid floating-point operations, such as dividing zero by zero.
- The finite set of non-zero values of the form $s * m * 2^e$, where s is 1 or -1, and m and e are determined by the particular floating-point type: For `float`, $0 < m < 2^{24}$ and $-149 \leq e \leq 104$, and for `double`, $0 < m < 2^{53}$ and $-1075 \leq e \leq 970$. Denormalized floating-point numbers are considered valid non-zero values.

The `float` type can represent values ranging from approximately $1.5 * 10^{-45}$ to $3.4 * 10^{38}$ with a precision of 7 digits.

The `double` type can represent values ranging from approximately $5.0 * 10^{-324}$ to $1.7 * 10^{308}$ with a precision of 15-16 digits.

If one of the operands of a binary operator is of a floating-point type, then the other operand must be of an integral type or a floating-point type, and the operation is evaluated as follows:

- If one of the operands is of an integral type, then that operand is converted to the floating-point type of the other operand.
- Then, if either of the operands is of type `double`, the other operand is converted to `double`, the operation is performed using at least `double` range and precision, and the type of the result is `double` (or `bool` for the relational operators).
- Otherwise, the operation is performed using at least `float` range and precision, and the type of the result is `float` (or `bool` for the relational operators).

The floating-point operators, including the assignment operators, never produce exceptions. Instead, in exceptional situations, floating-point operations produce zero, infinity, or NaN, as described below:

- If the result of a floating-point operation is too small for the destination format, the result of the operation becomes positive zero or negative zero.
- If the result of a floating-point operation is too large for the destination format, the result of the operation becomes positive infinity or negative infinity.
- If a floating-point operation is invalid, the result of the operation becomes NaN.
- If one or both operands of a floating-point operation is NaN, the result of the operation becomes NaN.

Floating-point operations may be performed with higher precision than the result type of the operation. For example, some hardware architectures support an "extended" or "long double" floating-point type with greater range and precision than the `double` type, and implicitly perform all floating-point operations using this higher precision type. Only at excessive cost in performance can such hardware architectures be made to perform floating-point operations with less precision, and rather than require an implementation to forfeit both performance and precision, C# allows a higher precision type to be used for all floating-point operations. Other than delivering more precise results, this rarely has any measurable effects. However, in expressions of the form $x * y / z$, where the multiplication produces a result that is outside the `double` range, but the subsequent division brings the temporary result back into the `double` range, the fact that the expression is evaluated in a higher range format may cause a finite result to be produced instead of an infinity.

The decimal type

The `decimal` type is a 128-bit data type suitable for financial and monetary calculations. The `decimal` type can represent values ranging from $1.0 * 10^{-28}$ to approximately $7.9 * 10^{28}$ with 28-29 significant digits.

The finite set of values of type `decimal` are of the form $(-1)^s * c * 10^{-e}$, where the sign s is 0 or 1, the coefficient c is given by $0 \leq c < 2^{96}$, and the scale e is such that $0 \leq e \leq 28$. The `decimal` type does not support signed zeros, infinities, or NaN's. A `decimal` is represented as a 96-bit integer scaled by a power of ten. For `decimal`s with an absolute value less than $1.0m$, the value is exact to the 28th decimal place, but no further. For `decimal`s with an absolute value greater than or equal to $1.0m$, the value is exact to 28 or 29 digits.

Contrary to the `float` and `double` data types, decimal fractional numbers such as 0.1 can be represented exactly in the `decimal` representation. In the `float` and `double` representations, such numbers are often infinite fractions, making those representations more prone to round-off errors.

If one of the operands of a binary operator is of type `decimal`, then the other operand must be of an integral type or of type `decimal`. If an integral type operand is present, it is converted to `decimal` before the operation is performed.

The result of an operation on values of type `decimal` is that which would result from calculating an exact result (preserving scale, as defined for each operator) and then rounding to fit the representation. Results are rounded to the nearest representable value, and, when a result is equally close to two representable values, to the value that has an even number in the least significant digit position (this is known as "banker's rounding"). A zero result always has a sign of 0 and a scale of 0.

If a decimal arithmetic operation produces a value less than or equal to $5 * 10^{-29}$ in absolute value, the result of the operation becomes zero. If a `decimal` arithmetic operation produces a result that is too large for the `decimal` format, a `System.OverflowException` is thrown.

The `decimal` type has greater precision but smaller range than the floating-point types. Thus, conversions from the floating-point types to `decimal` might produce overflow exceptions, and conversions from `decimal` to the floating-point types might cause loss of precision. For these reasons, no implicit conversions exist between the floating-point types and `decimal`, and without explicit casts, it is not possible to mix floating-point and `decimal` operands in the same expression.

The bool type

The `bool` type represents boolean logical quantities. The possible values of type `bool` are `true` and `false`.

No standard conversions exist between `bool` and other types. In particular, the `bool` type is distinct and separate from the integral types, and a `bool` value cannot be used in place of an integral value, and vice versa.

In the C and C++ languages, a zero integral or floating-point value, or a null pointer can be converted to the boolean value `false`, and a non-zero integral or floating-point value, or a non-null pointer can be converted to the boolean value `true`. In C#, such conversions are accomplished by explicitly comparing an integral or floating-point value to zero, or by explicitly comparing an object reference to `null`.

Enumeration types

An enumeration type is a distinct type with named constants. Every enumeration type has an underlying type, which must be `byte`, `sbyte`, `short`, `ushort`, `int`, `uint`, `long` or `ulong`. The set of values of the enumeration type is the same as the set of values of the underlying type. Values of the enumeration type are not restricted to the values of the named constants. Enumeration types are defined through enumeration declarations ([Enum declarations](#)).

Nullable types

A nullable type can represent all values of its *underlying type* plus an additional null value. A nullable type is written `T?`, where `T` is the underlying type. This syntax is shorthand for `System.Nullable<T>`, and the two forms can be used interchangeably.

A *non-nullable value type* conversely is any value type other than `System.Nullable<T>` and its shorthand `T?` (for any `T`), plus any type parameter that is constrained to be a non-nullable value type (that is, any type parameter with a `struct` constraint). The `System.Nullable<T>` type specifies the value type constraint for `T` ([Type parameter constraints](#)), which means that the underlying type of a nullable type can be any non-nullable value type. The underlying type of a nullable type cannot be a nullable type or a reference type. For example, `int??` and `string?` are invalid types.

An instance of a nullable type `T?` has two public read-only properties:

- A `HasValue` property of type `bool`
- A `Value` property of type `T`

An instance for which `HasValue` is true is said to be non-null. A non-null instance contains a known value and `Value` returns that value.

An instance for which `HasValue` is false is said to be null. A null instance has an undefined value. Attempting to read the `Value` of a null instance causes a `System.InvalidOperationException` to be thrown. The process of accessing the `Value` property of a nullable instance is referred to as *unwrapping*.

In addition to the default constructor, every nullable type `T?` has a public constructor that takes a single argument of type `T`. Given a value `x` of type `T`, a constructor invocation of the form

```
new T?(x)
```

creates a non-null instance of `T?` for which the `Value` property is `x`. The process of creating a non-null instance of a nullable type for a given value is referred to as *wrapping*.

Implicit conversions are available from the `null` literal to `T?` ([Null literal conversions](#)) and from `T` to `T?` ([Implicit nullable conversions](#)).

Reference types

A reference type is a class type, an interface type, an array type, or a delegate type.

```

reference_type
    : class_type
    | interface_type
    | array_type
    | delegate_type
    ;

class_type
    : type_name
    | 'object'
    | 'dynamic'
    | 'string'
    ;

interface_type
    : type_name
    ;

array_type
    : non_array_type rank_specifier+
    ;

non_array_type
    : type
    ;

rank_specifier
    : '[' dim_separator* ']'
    ;

dim_separator
    : ','
    ;

delegate_type
    : type_name
    ;

```

A reference type value is a reference to an *instance* of the type, the latter known as an *object*. The special value `null` is compatible with all reference types and indicates the absence of an instance.

Class types

A class type defines a data structure that contains data members (constants and fields), function members (methods, properties, events, indexers, operators, instance constructors, destructors and static constructors), and nested types. Class types support inheritance, a mechanism whereby derived classes can extend and specialize base classes. Instances of class types are created using *object_creation_expressions* ([Object creation expressions](#)).

Class types are described in [Classes](#).

Certain predefined class types have special meaning in the C# language, as described in the table below.

CLASS TYPE	DESCRIPTION
<code>System.Object</code>	The ultimate base class of all other types. See The object type .
<code>System.String</code>	The string type of the C# language. See The string type .
<code>System.ValueType</code>	The base class of all value types. See The System.ValueType type .

CLASS TYPE	DESCRIPTION
<code>System.Enum</code>	The base class of all enum types. See Enums .
<code>System.Array</code>	The base class of all array types. See Arrays .
<code>System.Delegate</code>	The base class of all delegate types. See Delegates .
<code>System.Exception</code>	The base class of all exception types. See Exceptions .

The object type

The `object` class type is the ultimate base class of all other types. Every type in C# directly or indirectly derives from the `object` class type.

The keyword `object` is simply an alias for the predefined class `System.Object`.

The dynamic type

The `dynamic` type, like `object`, can reference any object. When operators are applied to expressions of type `dynamic`, their resolution is deferred until the program is run. Thus, if the operator cannot legally be applied to the referenced object, no error is given during compilation. Instead an exception will be thrown when resolution of the operator fails at run-time.

Its purpose is to allow dynamic binding, which is described in detail in [Dynamic binding](#).

`dynamic` is considered identical to `object` except in the following respects:

- Operations on expressions of type `dynamic` can be dynamically bound ([Dynamic binding](#)).
- Type inference ([Type inference](#)) will prefer `dynamic` over `object` if both are candidates.

Because of this equivalence, the following holds:

- There is an implicit identity conversion between `object` and `dynamic`, and between constructed types that are the same when replacing `dynamic` with `object`.
- Implicit and explicit conversions to and from `object` also apply to and from `dynamic`.
- Method signatures that are the same when replacing `dynamic` with `object` are considered the same signature.
- The type `dynamic` is indistinguishable from `object` at run-time.
- An expression of the type `dynamic` is referred to as a *dynamic expression*.

The string type

The `string` type is a sealed class type that inherits directly from `object`. Instances of the `string` class represent Unicode character strings.

Values of the `string` type can be written as string literals ([String literals](#)).

The keyword `string` is simply an alias for the predefined class `System.String`.

Interface types

An interface defines a contract. A class or struct that implements an interface must adhere to its contract. An interface may inherit from multiple base interfaces, and a class or struct may implement multiple interfaces.

Interface types are described in [Interfaces](#).

Array types

An array is a data structure that contains zero or more variables which are accessed through computed indices.

The variables contained in an array, also called the elements of the array, are all of the same type, and this type is called the element type of the array.

Array types are described in [Arrays](#).

Delegate types

A delegate is a data structure that refers to one or more methods. For instance methods, it also refers to their corresponding object instances.

The closest equivalent of a delegate in C or C++ is a function pointer, but whereas a function pointer can only reference static functions, a delegate can reference both static and instance methods. In the latter case, the delegate stores not only a reference to the method's entry point, but also a reference to the object instance on which to invoke the method.

Delegate types are described in [Delegates](#).

Boxing and unboxing

The concept of boxing and unboxing is central to C#'s type system. It provides a bridge between *value_types* and *reference_types* by permitting any value of a *value_type* to be converted to and from type `object`. Boxing and unboxing enables a unified view of the type system wherein a value of any type can ultimately be treated as an object.

Boxing conversions

A boxing conversion permits a *value_type* to be implicitly converted to a *reference_type*. The following boxing conversions exist:

- From any *value_type* to the type `object`.
- From any *value_type* to the type `System.ValueType`.
- From any *non_nullable_value_type* to any *interface_type* implemented by the *value_type*.
- From any *nullable_type* to any *interface_type* implemented by the underlying type of the *nullable_type*.
- From any *enum_type* to the type `System.Enum`.
- From any *nullable_type* with an underlying *enum_type* to the type `System.Enum`.
- Note that an implicit conversion from a type parameter will be executed as a boxing conversion if at run-time it ends up converting from a value type to a reference type ([Implicit conversions involving type parameters](#)).

Boxing a value of a *non_nullable_value_type* consists of allocating an object instance and copying the *non_nullable_value_type* value into that instance.

Boxing a value of a *nullable_type* produces a null reference if it is the `null` value (`HasValue` is `false`), or the result of unwrapping and boxing the underlying value otherwise.

The actual process of boxing a value of a *non_nullable_value_type* is best explained by imagining the existence of a generic **boxing class**, which behaves as if it were declared as follows:

```
sealed class Box<T>: System.ValueType
{
    T value;

    public Box(T t) {
        value = t;
    }
}
```

Boxing of a value `v` of type `T` now consists of executing the expression `new Box<T>(v)`, and returning the resulting instance as a value of type `object`. Thus, the statements

```
int i = 123;
object box = i;
```

conceptually correspond to

```
int i = 123;
object box = new Box<int>(i);
```

A boxing class like `Box<T>` above doesn't actually exist and the dynamic type of a boxed value isn't actually a class type. Instead, a boxed value of type `T` has the dynamic type `T`, and a dynamic type check using the `is` operator can simply reference type `T`. For example,

```
int i = 123;
object box = i;
if (box is int) {
    Console.WriteLine("Box contains an int");
}
```

will output the string "`Box contains an int`" on the console.

A boxing conversion implies making a copy of the value being boxed. This is different from a conversion of a *reference_type* to type `object`, in which the value continues to reference the same instance and simply is regarded as the less derived type `object`. For example, given the declaration

```
struct Point
{
    public int x, y;

    public Point(int x, int y) {
        this.x = x;
        this.y = y;
    }
}
```

the following statements

```
Point p = new Point(10, 10);
object box = p;
p.x = 20;
Console.WriteLine(((Point)box).x);
```

will output the value 10 on the console because the implicit boxing operation that occurs in the assignment of `p` to `box` causes the value of `p` to be copied. Had `Point` been declared a `class` instead, the value 20 would be output because `p` and `box` would reference the same instance.

Unboxing conversions

An unboxing conversion permits a *reference_type* to be explicitly converted to a *value_type*. The following unboxing conversions exist:

- From the type `object` to any *value_type*.
- From the type `System.ValueType` to any *value_type*.
- From any *interface_type* to any *non_nullable_value_type* that implements the *interface_type*.
- From any *interface_type* to any *nullable_type* whose underlying type implements the *interface_type*.
- From the type `System.Enum` to any *enum_type*.

- From the type `System.Enum` to any *nullable_type* with an underlying *enum_type*.
- Note that an explicit conversion to a type parameter will be executed as an unboxing conversion if at run-time it ends up converting from a reference type to a value type ([Explicit dynamic conversions](#)).

An unboxing operation to a *non_nullable_value_type* consists of first checking that the object instance is a boxed value of the given *non_nullable_value_type*, and then copying the value out of the instance.

Unboxing to a *nullable_type* produces the null value of the *nullable_type* if the source operand is `null`, or the wrapped result of unboxing the object instance to the underlying type of the *nullable_type* otherwise.

Referring to the imaginary boxing class described in the previous section, an unboxing conversion of an object `box` to a *value_type* `T` consists of executing the expression `((Box<T>)box).value`. Thus, the statements

```
object box = 123;
int i = (int)box;
```

conceptually correspond to

```
object box = new Box<int>(123);
int i = ((Box<int>)box).value;
```

For an unboxing conversion to a given *non_nullable_value_type* to succeed at run-time, the value of the source operand must be a reference to a boxed value of that *non_nullable_value_type*. If the source operand is `null`, a `System.NullReferenceException` is thrown. If the source operand is a reference to an incompatible object, a `System.InvalidCastException` is thrown.

For an unboxing conversion to a given *nullable_type* to succeed at run-time, the value of the source operand must be either `null` or a reference to a boxed value of the underlying *non_nullable_value_type* of the *nullable_type*. If the source operand is a reference to an incompatible object, a `System.InvalidCastException` is thrown.

Constructed types

A generic type declaration, by itself, denotes an *unbound generic type* that is used as a "blueprint" to form many different types, by way of applying *type arguments*. The type arguments are written within angle brackets (`<` and `>`) immediately following the name of the generic type. A type that includes at least one type argument is called a *constructed type*. A constructed type can be used in most places in the language in which a type name can appear. An unbound generic type can only be used within a *typeof_expression* ([The typeof operator](#)).

Constructed types can also be used in expressions as simple names ([Simple names](#)) or when accessing a member ([Member access](#)).

When a *namespace_or_type_name* is evaluated, only generic types with the correct number of type parameters are considered. Thus, it is possible to use the same identifier to identify different types, as long as the types have different numbers of type parameters. This is useful when mixing generic and non-generic classes in the same program:

```

namespace Widgets
{
    class Queue {...}
    class Queue<TElement> {...}
}

namespace MyApplication
{
    using Widgets;

    class X
    {
        Queue q1;           // Non-generic Widgets.Queue
        Queue<int> q2;       // Generic Widgets.Queue
    }
}

```

A *type_name* might identify a constructed type even though it doesn't specify type parameters directly. This can occur where a type is nested within a generic class declaration, and the instance type of the containing declaration is implicitly used for name lookup ([Nested types in generic classes](#)):

```

class Outer<T>
{
    public class Inner {...}

    public Inner i;           // Type of i is Outer<T>.Inner
}

```

In unsafe code, a constructed type cannot be used as an *unmanaged_type* ([Pointer types](#)).

Type arguments

Each argument in a type argument list is simply a *type*.

```

type_argument_list
    : '<' type_arguments '>'
    ;

type_arguments
    : type_argument (',' type_argument)*
    ;

type_argument
    : type
    ;

```

In unsafe code ([Unsafe code](#)), a *type_argument* may not be a pointer type. Each type argument must satisfy any constraints on the corresponding type parameter ([Type parameter constraints](#)).

Open and closed types

All types can be classified as either *open types* or *closed types*. An open type is a type that involves type parameters. More specifically:

- A type parameter defines an open type.
- An array type is an open type if and only if its element type is an open type.
- A constructed type is an open type if and only if one or more of its type arguments is an open type. A constructed nested type is an open type if and only if one or more of its type arguments or the type arguments of its containing type(s) is an open type.

A closed type is a type that is not an open type.

At run-time, all of the code within a generic type declaration is executed in the context of a closed constructed type that was created by applying type arguments to the generic declaration. Each type parameter within the generic type is bound to a particular run-time type. The run-time processing of all statements and expressions always occurs with closed types, and open types occur only during compile-time processing.

Each closed constructed type has its own set of static variables, which are not shared with any other closed constructed types. Since an open type does not exist at run-time, there are no static variables associated with an open type. Two closed constructed types are the same type if they are constructed from the same unbound generic type, and their corresponding type arguments are the same type.

Bound and unbound types

The term **unbound type** refers to a non-generic type or an unbound generic type. The term **bound type** refers to a non-generic type or a constructed type.

An unbound type refers to the entity declared by a type declaration. An unbound generic type is not itself a type, and cannot be used as the type of a variable, argument or return value, or as a base type. The only construct in which an unbound generic type can be referenced is the `typeof` expression ([The typeof operator](#)).

Satisfying constraints

Whenever a constructed type or generic method is referenced, the supplied type arguments are checked against the type parameter constraints declared on the generic type or method ([Type parameter constraints](#)). For each `where` clause, the type argument `A` that corresponds to the named type parameter is checked against each constraint as follows:

- If the constraint is a class type, an interface type, or a type parameter, let `C` represent that constraint with the supplied type arguments substituted for any type parameters that appear in the constraint. To satisfy the constraint, it must be the case that type `A` is convertible to type `C` by one of the following:
 - An identity conversion ([Identity conversion](#))
 - An implicit reference conversion ([Implicit reference conversions](#))
 - A boxing conversion ([Boxing conversions](#)), provided that type `A` is a non-nullable value type.
 - An implicit reference, boxing or type parameter conversion from a type parameter `A` to `C`.
- If the constraint is the reference type constraint (`class`), the type `A` must satisfy one of the following:
 - `A` is an interface type, class type, delegate type or array type. Note that `System.ValueType` and `System.Enum` are reference types that satisfy this constraint.
 - `A` is a type parameter that is known to be a reference type ([Type parameter constraints](#)).
- If the constraint is the value type constraint (`struct`), the type `A` must satisfy one of the following:
 - `A` is a struct type or enum type, but not a nullable type. Note that `System.ValueType` and `System.Enum` are reference types that do not satisfy this constraint.
 - `A` is a type parameter having the value type constraint ([Type parameter constraints](#)).
- If the constraint is the constructor constraint (`new()`), the type `A` must not be `abstract` and must have a public parameterless constructor. This is satisfied if one of the following is true:
 - `A` is a value type, since all value types have a public default constructor ([Default constructors](#)).
 - `A` is a type parameter having the constructor constraint ([Type parameter constraints](#)).
 - `A` is a type parameter having the value type constraint ([Type parameter constraints](#)).
 - `A` is a class that is not `abstract` and contains an explicitly declared `public` constructor with no parameters.
 - `A` is not `abstract` and has a default constructor ([Default constructors](#)).

A compile-time error occurs if one or more of a type parameter's constraints are not satisfied by the given type arguments.

Since type parameters are not inherited, constraints are never inherited either. In the example below, `D` needs to specify the constraint on its type parameter `T` so that `T` satisfies the constraint imposed by the base class `B<T>`. In contrast, class `E` need not specify a constraint, because `List<T>` implements `IEnumerable` for any `T`.

```
class B<T> where T: IEnumerable {...}

class D<T>: B<T> where T: IEnumerable {...}

class E<T>: B<List<T>> {...}
```

Type parameters

A type parameter is an identifier designating a value type or reference type that the parameter is bound to at run-time.

```
type_parameter
: identifier
;
```

Since a type parameter can be instantiated with many different actual type arguments, type parameters have slightly different operations and restrictions than other types. These include:

- A type parameter cannot be used directly to declare a base class ([Base class](#)) or interface ([Variant type parameter lists](#)).
- The rules for member lookup on type parameters depend on the constraints, if any, applied to the type parameter. They are detailed in [Member lookup](#).
- The available conversions for a type parameter depend on the constraints, if any, applied to the type parameter. They are detailed in [Implicit conversions involving type parameters](#) and [Explicit dynamic conversions](#).
- The literal `null` cannot be converted to a type given by a type parameter, except if the type parameter is known to be a reference type ([Implicit conversions involving type parameters](#)). However, a `default` expression ([Default value expressions](#)) can be used instead. In addition, a value with a type given by a type parameter can be compared with `null` using `==` and `!=` ([Reference type equality operators](#)) unless the type parameter has the value type constraint.
- A `new` expression ([Object creation expressions](#)) can only be used with a type parameter if the type parameter is constrained by a *constructor_constraint* or the value type constraint ([Type parameter constraints](#)).
- A type parameter cannot be used anywhere within an attribute.
- A type parameter cannot be used in a member access ([Member access](#)) or type name ([Namespace and type names](#)) to identify a static member or a nested type.
- In unsafe code, a type parameter cannot be used as an *unmanaged_type* ([Pointer types](#)).

As a type, type parameters are purely a compile-time construct. At run-time, each type parameter is bound to a run-time type that was specified by supplying a type argument to the generic type declaration. Thus, the type of a variable declared with a type parameter will, at run-time, be a closed constructed type ([Open and closed types](#)). The run-time execution of all statements and expressions involving type parameters uses the actual type that was supplied as the type argument for that parameter.

Expression tree types

Expression trees permit lambda expressions to be represented as data structures instead of executable code.

Expression trees are values of *expression tree types* of the form `System.Linq.Expressions.Expression<D>`,

where `D` is any delegate type. For the remainder of this specification we will refer to these types using the shorthand `Expression<D>`.

If a conversion exists from a lambda expression to a delegate type `D`, a conversion also exists to the expression tree type `Expression<D>`. Whereas the conversion of a lambda expression to a delegate type generates a delegate that references executable code for the lambda expression, conversion to an expression tree type creates an expression tree representation of the lambda expression.

Expression trees are efficient in-memory data representations of lambda expressions and make the structure of the lambda expression transparent and explicit.

Just like a delegate type `D`, `Expression<D>` is said to have parameter and return types, which are the same as those of `D`.

The following example represents a lambda expression both as executable code and as an expression tree.

Because a conversion exists to `Func<int,int>`, a conversion also exists to `Expression<Func<int,int>>`:

```
Func<int,int> del = x => x + 1;           // Code

Expression<Func<int,int>> exp = x => x + 1; // Data
```

Following these assignments, the delegate `del` references a method that returns `x + 1`, and the expression tree `exp` references a data structure that describes the expression `x => x + 1`.

The exact definition of the generic type `Expression<D>` as well as the precise rules for constructing an expression tree when a lambda expression is converted to an expression tree type, are both outside the scope of this specification.

Two things are important to make explicit:

- Not all lambda expressions can be converted to expression trees. For instance, lambda expressions with statement bodies, and lambda expressions containing assignment expressions cannot be represented. In these cases, a conversion still exists, but will fail at compile-time. These exceptions are detailed in [Anonymous function conversions](#).
- `Expression<D>` offers an instance method `Compile` which produces a delegate of type `D`:

```
Func<int,int> del2 = exp.Compile();
```

Invoking this delegate causes the code represented by the expression tree to be executed. Thus, given the definitions above, `del` and `del2` are equivalent, and the following two statements will have the same effect:

```
int i1 = del(1);

int i2 = del2(1);
```

After executing this code, `i1` and `i2` will both have the value `2`.

Variables

12/28/2021 • 32 minutes to read • [Edit Online](#)

Variables represent storage locations. Every variable has a type that determines what values can be stored in the variable. C# is a type-safe language, and the C# compiler guarantees that values stored in variables are always of the appropriate type. The value of a variable can be changed through assignment or through use of the `++` and `--` operators.

A variable must be *definitely assigned* ([Definite assignment](#)) before its value can be obtained.

As described in the following sections, variables are either *initially assigned* or *initially unassigned*. An initially assigned variable has a well-defined initial value and is always considered definitely assigned. An initially unassigned variable has no initial value. For an initially unassigned variable to be considered definitely assigned at a certain location, an assignment to the variable must occur in every possible execution path leading to that location.

Variable categories

C# defines seven categories of variables: static variables, instance variables, array elements, value parameters, reference parameters, output parameters, and local variables. The sections that follow describe each of these categories.

In the example

```
class A
{
    public static int x;
    int y;

    void F(int[] v, int a, ref int b, out int c) {
        int i = 1;
        c = a + b++;
    }
}
```

`x` is a static variable, `y` is an instance variable, `v[0]` is an array element, `a` is a value parameter, `b` is a reference parameter, `c` is an output parameter, and `i` is a local variable.

Static variables

A field declared with the `static` modifier is called a *static variable*. A static variable comes into existence before execution of the static constructor ([Static constructors](#)) for its containing type, and ceases to exist when the associated application domain ceases to exist.

The initial value of a static variable is the default value ([Default values](#)) of the variable's type.

For purposes of definite assignment checking, a static variable is considered initially assigned.

Instance variables

A field declared without the `static` modifier is called an *instance variable*.

Instance variables in classes

An instance variable of a class comes into existence when a new instance of that class is created, and ceases to exist when there are no references to that instance and the instance's destructor (if any) has executed.

The initial value of an instance variable of a class is the default value ([Default values](#)) of the variable's type.

For the purpose of definite assignment checking, an instance variable of a class is considered initially assigned.

Instance variables in structs

An instance variable of a struct has exactly the same lifetime as the struct variable to which it belongs. In other words, when a variable of a struct type comes into existence or ceases to exist, so too do the instance variables of the struct.

The initial assignment state of an instance variable of a struct is the same as that of the containing struct variable. In other words, when a struct variable is considered initially assigned, so too are its instance variables, and when a struct variable is considered initially unassigned, its instance variables are likewise unassigned.

Array elements

The elements of an array come into existence when an array instance is created, and cease to exist when there are no references to that array instance.

The initial value of each of the elements of an array is the default value ([Default values](#)) of the type of the array elements.

For the purpose of definite assignment checking, an array element is considered initially assigned.

Value parameters

A parameter declared without a `ref` or `out` modifier is a *value parameter*.

A value parameter comes into existence upon invocation of the function member (method, instance constructor, accessor, or operator) or anonymous function to which the parameter belongs, and is initialized with the value of the argument given in the invocation. A value parameter normally ceases to exist upon return of the function member or anonymous function. However, if the value parameter is captured by an anonymous function ([Anonymous function expressions](#)), its life time extends at least until the delegate or expression tree created from that anonymous function is eligible for garbage collection.

For the purpose of definite assignment checking, a value parameter is considered initially assigned.

Reference parameters

A parameter declared with a `ref` modifier is a *reference parameter*.

A reference parameter does not create a new storage location. Instead, a reference parameter represents the same storage location as the variable given as the argument in the function member or anonymous function invocation. Thus, the value of a reference parameter is always the same as the underlying variable.

The following definite assignment rules apply to reference parameters. Note the different rules for output parameters described in [Output parameters](#).

- A variable must be definitely assigned ([Definite assignment](#)) before it can be passed as a reference parameter in a function member or delegate invocation.
- Within a function member or anonymous function, a reference parameter is considered initially assigned.

Within an instance method or instance accessor of a struct type, the `this` keyword behaves exactly as a reference parameter of the struct type ([This access](#)).

Output parameters

A parameter declared with an `out` modifier is an *output parameter*.

An output parameter does not create a new storage location. Instead, an output parameter represents the same storage location as the variable given as the argument in the function member or delegate invocation. Thus, the value of an output parameter is always the same as the underlying variable.

The following definite assignment rules apply to output parameters. Note the different rules for reference parameters described in [Reference parameters](#).

- A variable need not be definitely assigned before it can be passed as an output parameter in a function member or delegate invocation.
- Following the normal completion of a function member or delegate invocation, each variable that was passed as an output parameter is considered assigned in that execution path.
- Within a function member or anonymous function, an output parameter is considered initially unassigned.
- Every output parameter of a function member or anonymous function must be definitely assigned ([Definite assignment](#)) before the function member or anonymous function returns normally.

Within an instance constructor of a struct type, the `this` keyword behaves exactly as an output parameter of the struct type ([This access](#)).

Local variables

A **local variable** is declared by a *local_variable_declaration*, which may occur in a *block*, a *for_statement*, a *switch_statement* or a *using_statement*, or by a *foreach_statement* or a *specific_catch_clause* for a *try_statement*.

The lifetime of a local variable is the portion of program execution during which storage is guaranteed to be reserved for it. This lifetime extends at least from entry into the *block*, *for_statement*, *switch_statement*, *using_statement*, *foreach_statement*, or *specific_catch_clause* with which it is associated, until execution of that *block*, *for_statement*, *switch_statement*, *using_statement*, *foreach_statement*, or *specific_catch_clause* ends in any way. (Entering an enclosed *block* or calling a method suspends, but does not end, execution of the current *block*, *for_statement*, *switch_statement*, *using_statement*, *foreach_statement*, or *specific_catch_clause*.) If the local variable is captured by an anonymous function ([Captured outer variables](#)), its lifetime extends at least until the delegate or expression tree created from the anonymous function, along with any other objects that come to reference the captured variable, are eligible for garbage collection.

If the parent *block*, *for_statement*, *switch_statement*, *using_statement*, *foreach_statement*, or *specific_catch_clause* is entered recursively, a new instance of the local variable is created each time, and its *local_variable_initializer*, if any, is evaluated each time.

A local variable introduced by a *local_variable_declaration* is not automatically initialized and thus has no default value. For the purpose of definite assignment checking, a local variable introduced by a *local_variable_declaration* is considered initially unassigned. A *local_variable_declaration* may include a *local_variable_initializer*, in which case the variable is considered definitely assigned only after the initializing expression ([Declaration statements](#)).

Within the scope of a local variable introduced by a *local_variable_declaration*, it is a compile-time error to refer to that local variable in a textual position that precedes its *local_variable_declarator*. If the local variable declaration is implicit ([Local variable declarations](#)), it is also an error to refer to the variable within its *local_variable_declarator*.

A local variable introduced by a *foreach_statement* or a *specific_catch_clause* is considered definitely assigned in its entire scope.

The actual lifetime of a local variable is implementation-dependent. For example, a compiler might statically determine that a local variable in a block is only used for a small portion of that block. Using this analysis, the compiler could generate code that results in the variable's storage having a shorter lifetime than its containing block.

The storage referred to by a local reference variable is reclaimed independently of the lifetime of that local reference variable ([Automatic memory management](#)).

Default values

The following categories of variables are automatically initialized to their default values:

- Static variables.
- Instance variables of class instances.
- Array elements.

The default value of a variable depends on the type of the variable and is determined as follows:

- For a variable of a *value_type*, the default value is the same as the value computed by the *value_type*'s default constructor ([Default constructors](#)).
- For a variable of a *reference_type*, the default value is `null`.

Initialization to default values is typically done by having the memory manager or garbage collector initialize memory to all-bits-zero before it is allocated for use. For this reason, it is convenient to use all-bits-zero to represent the null reference.

Definite assignment

At a given location in the executable code of a function member, a variable is said to be *definitely assigned* if the compiler can prove, by a particular static flow analysis ([Precise rules for determining definite assignment](#)), that the variable has been automatically initialized or has been the target of at least one assignment. Informally stated, the rules of definite assignment are:

- An initially assigned variable ([Initially assigned variables](#)) is always considered definitely assigned.
- An initially unassigned variable ([Initially unassigned variables](#)) is considered definitely assigned at a given location if all possible execution paths leading to that location contain at least one of the following:
 - A simple assignment ([Simple assignment](#)) in which the variable is the left operand.
 - An invocation expression ([Invocation expressions](#)) or object creation expression ([Object creation expressions](#)) that passes the variable as an output parameter.
 - For a local variable, a local variable declaration ([Local variable declarations](#)) that includes a variable initializer.

The formal specification underlying the above informal rules is described in [Initially assigned variables](#), [Initially unassigned variables](#), and [Precise rules for determining definite assignment](#).

The definite assignment states of instance variables of a *struct_type* variable are tracked individually as well as collectively. In addition to the rules above, the following rules apply to *struct_type* variables and their instance variables:

- An instance variable is considered definitely assigned if its containing *struct_type* variable is considered definitely assigned.
- A *struct_type* variable is considered definitely assigned if each of its instance variables is considered definitely assigned.

Definite assignment is a requirement in the following contexts:

- A variable must be definitely assigned at each location where its value is obtained. This ensures that undefined values never occur. The occurrence of a variable in an expression is considered to obtain the value of the variable, except when
 - the variable is the left operand of a simple assignment,
 - the variable is passed as an output parameter, or
 - the variable is a *struct_type* variable and occurs as the left operand of a member access.
- A variable must be definitely assigned at each location where it is passed as a reference parameter. This ensures that the function member being invoked can consider the reference parameter initially assigned.
- All output parameters of a function member must be definitely assigned at each location where the function

member returns (through a `return` statement or through execution reaching the end of the function member body). This ensures that function members do not return undefined values in output parameters, thus enabling the compiler to consider a function member invocation that takes a variable as an output parameter equivalent to an assignment to the variable.

- The `this` variable of a *struct_type* instance constructor must be definitely assigned at each location where that instance constructor returns.

Initially assigned variables

The following categories of variables are classified as initially assigned:

- Static variables.
- Instance variables of class instances.
- Instance variables of initially assigned struct variables.
- Array elements.
- Value parameters.
- Reference parameters.
- Variables declared in a `catch` clause or a `foreach` statement.

Initially unassigned variables

The following categories of variables are classified as initially unassigned:

- Instance variables of initially unassigned struct variables.
- Output parameters, including the `this` variable of struct instance constructors.
- Local variables, except those declared in a `catch` clause or a `foreach` statement.

Precise rules for determining definite assignment

In order to determine that each used variable is definitely assigned, the compiler must use a process that is equivalent to the one described in this section.

The compiler processes the body of each function member that has one or more initially unassigned variables. For each initially unassigned variable v , the compiler determines a ***definite assignment state*** for v at each of the following points in the function member:

- At the beginning of each statement
- At the end point ([End points and reachability](#)) of each statement
- On each arc which transfers control to another statement or to the end point of a statement
- At the beginning of each expression
- At the end of each expression

The definite assignment state of v can be either:

- Definitely assigned. This indicates that on all possible control flows to this point, v has been assigned a value.
- Not definitely assigned. For the state of a variable at the end of an expression of type `bool`, the state of a variable that isn't definitely assigned may (but doesn't necessarily) fall into one of the following sub-states:
 - Definitely assigned after true expression. This state indicates that v is definitely assigned if the boolean expression evaluated as true, but is not necessarily assigned if the boolean expression evaluated as false.
 - Definitely assigned after false expression. This state indicates that v is definitely assigned if the boolean expression evaluated as false, but is not necessarily assigned if the boolean expression evaluated as true.

The following rules govern how the state of a variable v is determined at each location.

General rules for statements

- v is not definitely assigned at the beginning of a function member body.
- v is definitely assigned at the beginning of any unreachable statement.
- The definite assignment state of v at the beginning of any other statement is determined by checking the definite assignment state of v on all control flow transfers that target the beginning of that statement. If (and only if) v is definitely assigned on all such control flow transfers, then v is definitely assigned at the beginning of the statement. The set of possible control flow transfers is determined in the same way as for checking statement reachability ([End points and reachability](#)).
- The definite assignment state of v at the end point of a block, `checked`, `unchecked`, `if`, `while`, `do`, `for`, `foreach`, `lock`, `using`, or `switch` statement is determined by checking the definite assignment state of v on all control flow transfers that target the end point of that statement. If v is definitely assigned on all such control flow transfers, then v is definitely assigned at the end point of the statement. Otherwise, v is not definitely assigned at the end point of the statement. The set of possible control flow transfers is determined in the same way as for checking statement reachability ([End points and reachability](#)).

Block statements, checked, and unchecked statements

The definite assignment state of v on the control transfer to the first statement of the statement list in the block (or to the end point of the block, if the statement list is empty) is the same as the definite assignment statement of v before the block, `checked`, or `unchecked` statement.

Expression statements

For an expression statement *stmt* that consists of the expression *expr*:

- v has the same definite assignment state at the beginning of *expr* as at the beginning of *stmt*.
- If v is definitely assigned at the end of *expr*, it is definitely assigned at the end point of *stmt*; otherwise, it is not definitely assigned at the end point of *stmt*.

Declaration statements

- If *stmt* is a declaration statement without initializers, then v has the same definite assignment state at the end point of *stmt* as at the beginning of *stmt*.
- If *stmt* is a declaration statement with initializers, then the definite assignment state for v is determined as if *stmt* were a statement list, with one assignment statement for each declaration with an initializer (in the order of declaration).

If statements

For an `if` statement *stmt* of the form:

```
if ( expr ) then_stmt else else_stmt
```

- v has the same definite assignment state at the beginning of *expr* as at the beginning of *stmt*.
- If v is definitely assigned at the end of *expr*, then it is definitely assigned on the control flow transfer to *then_stmt* and to either *else_stmt* or to the end-point of *stmt* if there is no else clause.
- If v has the state "definitely assigned after true expression" at the end of *expr*, then it is definitely assigned on the control flow transfer to *then_stmt*, and not definitely assigned on the control flow transfer to either *else_stmt* or to the end-point of *stmt* if there is no else clause.
- If v has the state "definitely assigned after false expression" at the end of *expr*, then it is definitely assigned on the control flow transfer to *else_stmt*, and not definitely assigned on the control flow transfer to *then_stmt*. It is definitely assigned at the end-point of *stmt* if and only if it is definitely assigned at the end-point of *then_stmt*.
- Otherwise, v is considered not definitely assigned on the control flow transfer to either the *then_stmt* or *else_stmt*, or to the end-point of *stmt* if there is no else clause.

Switch statements

In a `switch` statement *stmt* with a controlling expression *expr*:

- The definite assignment state of v at the beginning of $expr$ is the same as the state of v at the beginning of $stmt$.
- The definite assignment state of v on the control flow transfer to a reachable switch block statement list is the same as the definite assignment state of v at the end of $expr$.

While statements

For a `while` statement $stmt$ of the form:

```
while ( expr ) while_body
```

- v has the same definite assignment state at the beginning of $expr$ as at the beginning of $stmt$.
- If v is definitely assigned at the end of $expr$, then it is definitely assigned on the control flow transfer to $while_body$ and to the end point of $stmt$.
- If v has the state "definitely assigned after true expression" at the end of $expr$, then it is definitely assigned on the control flow transfer to $while_body$, but not definitely assigned at the end-point of $stmt$.
- If v has the state "definitely assigned after false expression" at the end of $expr$, then it is definitely assigned on the control flow transfer to the end point of $stmt$, but not definitely assigned on the control flow transfer to $while_body$.

Do statements

For a `do` statement $stmt$ of the form:

```
do do_body while ( expr ) ;
```

- v has the same definite assignment state on the control flow transfer from the beginning of $stmt$ to do_body as at the beginning of $stmt$.
- v has the same definite assignment state at the beginning of $expr$ as at the end point of do_body .
- If v is definitely assigned at the end of $expr$, then it is definitely assigned on the control flow transfer to the end point of $stmt$.
- If v has the state "definitely assigned after false expression" at the end of $expr$, then it is definitely assigned on the control flow transfer to the end point of $stmt$.

For statements

Definite assignment checking for a `for` statement of the form:

```
for ( for_initializer ; for_condition ; for_iterator ) embedded_statement
```

is done as if the statement were written:

```
{
    for_initializer ;
    while ( for_condition ) {
        embedded_statement ;
        for_iterator ;
    }
}
```

If the *for_condition* is omitted from the `for` statement, then evaluation of definite assignment proceeds as if *for_condition* were replaced with `true` in the above expansion.

Break, continue, and goto statements

The definite assignment state of v on the control flow transfer caused by a `break`, `continue`, or `goto` statement is the same as the definite assignment state of v at the beginning of the statement.

Throw statements

For a statement *stmt* of the form

```
throw expr ;
```

The definite assignment state of *v* at the beginning of *expr* is the same as the definite assignment state of *v* at the beginning of *stmt*.

Return statements

For a statement *stmt* of the form

```
return expr ;
```

- The definite assignment state of *v* at the beginning of *expr* is the same as the definite assignment state of *v* at the beginning of *stmt*.
- If *v* is an output parameter, then it must be definitely assigned either:
 - after *expr*
 - or at the end of the `finally` block of a `try - finally` or `try - catch - finally` that encloses the `return` statement.

For a statement *stmt* of the form:

```
return ;
```

- If *v* is an output parameter, then it must be definitely assigned either:
 - before *stmt*
 - or at the end of the `finally` block of a `try - finally` or `try - catch - finally` that encloses the `return` statement.

Try-catch statements

For a statement *stmt* of the form:

```
try try_block  
catch(...) catch_block_1  
...  
catch(...) catch_block_n
```

- The definite assignment state of *v* at the beginning of *try_block* is the same as the definite assignment state of *v* at the beginning of *stmt*.
- The definite assignment state of *v* at the beginning of *catch_block_i* (for any *i*) is the same as the definite assignment state of *v* at the beginning of *stmt*.
- The definite assignment state of *v* at the end-point of *stmt* is definitely assigned if (and only if) *v* is definitely assigned at the end-point of *try_block* and every *catch_block_i* (for every *i* from 1 to *n*).

Try-finally statements

For a `try` statement *stmt* of the form:

```
try try_block finally finally_block
```

- The definite assignment state of *v* at the beginning of *try_block* is the same as the definite assignment state of *v* at the beginning of *stmt*.

- The definite assignment state of v at the beginning of *finally_block* is the same as the definite assignment state of v at the beginning of *stmt*.
- The definite assignment state of v at the end-point of *stmt* is definitely assigned if (and only if) at least one of the following is true:
 - v is definitely assigned at the end-point of *try_block*
 - v is definitely assigned at the end-point of *finally_block*

If a control flow transfer (for example, a `goto` statement) is made that begins within *try_block*, and ends outside of *try_block*, then v is also considered definitely assigned on that control flow transfer if v is definitely assigned at the end-point of *finally_block*. (This is not an only if—if v is definitely assigned for another reason on this control flow transfer, then it is still considered definitely assigned.)

Try-catch-finally statements

Definite assignment analysis for a `try` - `catch` - `finally` statement of the form:

```
try try_block
catch(...) catch_block_1
...
catch(...) catch_block_n
finally *finally_block*
```

is done as if the statement were a `try` - `finally` statement enclosing a `try` - `catch` statement:

```
try {
    try try_block
    catch(...) catch_block_1
    ...
    catch(...) catch_block_n
}
finally finally_block
```

The following example demonstrates how the different blocks of a `try` statement ([The try statement](#)) affect definite assignment.

```

class A
{
    static void F() {
        int i, j;
        try {
            goto LABEL;
            // neither i nor j definitely assigned
            i = 1;
            // i definitely assigned
        }

        catch {
            // neither i nor j definitely assigned
            i = 3;
            // i definitely assigned
        }

        finally {
            // neither i nor j definitely assigned
            j = 5;
            // j definitely assigned
        }
        // i and j definitely assigned
    LABEL:;
        // j definitely assigned
    }
}

```

Foreach statements

For a `foreach` statement *stmt* of the form:

```
foreach ( type identifier in expr ) embedded_statement
```

- The definite assignment state of *v* at the beginning of *expr* is the same as the state of *v* at the beginning of *stmt*.
- The definite assignment state of *v* on the control flow transfer to *embedded_statement* or to the end point of *stmt* is the same as the state of *v* at the end of *expr*.

Using statements

For a `using` statement *stmt* of the form:

```
using ( resource_acquisition ) embedded_statement
```

- The definite assignment state of *v* at the beginning of *resource_acquisition* is the same as the state of *v* at the beginning of *stmt*.
- The definite assignment state of *v* on the control flow transfer to *embedded_statement* is the same as the state of *v* at the end of *resource_acquisition*.

Lock statements

For a `lock` statement *stmt* of the form:

```
lock ( expr ) embedded_statement
```

- The definite assignment state of *v* at the beginning of *expr* is the same as the state of *v* at the beginning of *stmt*.
- The definite assignment state of *v* on the control flow transfer to *embedded_statement* is the same as the

state of v at the end of *expr*.

Yield statements

For a `yield return` statement *stmt* of the form:

```
yield return expr ;
```

- The definite assignment state of v at the beginning of *expr* is the same as the state of v at the beginning of *stmt*.
- The definite assignment state of v at the end of *stmt* is the same as the state of v at the end of *expr*.
- A `yield break` statement has no effect on the definite assignment state.

General rules for simple expressions

The following rule applies to these kinds of expressions: literals ([Literals](#)), simple names ([Simple names](#)), member access expressions ([Member access](#)), non-indexed base access expressions ([Base access](#)), `typeof` expressions ([The typeof operator](#)), default value expressions ([Default value expressions](#)) and `nameof` expressions ([Nameof expressions](#)).

- The definite assignment state of v at the end of such an expression is the same as the definite assignment state of v at the beginning of the expression.

General rules for expressions with embedded expressions

The following rules apply to these kinds of expressions: parenthesized expressions ([Parenthesized expressions](#)), element access expressions ([Element access](#)), base access expressions with indexing ([Base access](#)), increment and decrement expressions ([Postfix increment and decrement operators](#), [Prefix increment and decrement operators](#)), cast expressions ([Cast expressions](#)), unary `+`, `-`, `~`, `*` expressions, binary `+`, `-`, `*`, `/`, `%`, `<<`, `>>`, `<`, `<=`, `>`, `>=`, `==`, `!=`, `is`, `as`, `&`, `|`, `^` expressions ([Arithmetic operators](#), [Shift operators](#), [Relational and type-testing operators](#), [Logical operators](#)), compound assignment expressions ([Compound assignment](#)), `checked` and `unchecked` expressions ([The checked and unchecked operators](#)), plus array and delegate creation expressions ([The new operator](#)).

Each of these expressions has one or more sub-expressions that are unconditionally evaluated in a fixed order. For example, the binary `%` operator evaluates the left hand side of the operator, then the right hand side. An indexing operation evaluates the indexed expression, and then evaluates each of the index expressions, in order from left to right. For an expression *expr*, which has sub-expressions *e1*, *e2*, ..., *eN*, evaluated in that order:

- The definite assignment state of v at the beginning of *e1* is the same as the definite assignment state at the beginning of *expr*.
- The definite assignment state of v at the beginning of *ei* (*i* greater than one) is the same as the definite assignment state at the end of the previous sub-expression.
- The definite assignment state of v at the end of *expr* is the same as the definite assignment state at the end of *eN*.

Invocation expressions and object creation expressions

For an invocation expression *expr* of the form:

```
primary_expression ( arg1 , arg2 , ... , argN )
```

or an object creation expression of the form:

```
new type ( arg1 , arg2 , ... , argN )
```

- For an invocation expression, the definite assignment state of v before *primary_expression* is the same as the

state of v before $expr$.

- For an invocation expression, the definite assignment state of v before $arg1$ is the same as the state of v after $primary_expression$.
- For an object creation expression, the definite assignment state of v before $arg1$ is the same as the state of v before $expr$.
- For each argument arg_i , the definite assignment state of v after arg_i is determined by the normal expression rules, ignoring any `ref` or `out` modifiers.
- For each argument arg_i for any i greater than one, the definite assignment state of v before arg_i is the same as the state of v after the previous arg .
- If the variable v is passed as an `out` argument (i.e., an argument of the form `out v`) in any of the arguments, then the state of v after $expr$ is definitely assigned. Otherwise; the state of v after $expr$ is the same as the state of v after $argN$.
- For array initializers ([Array creation expressions](#)), object initializers ([Object initializers](#)), collection initializers ([Collection initializers](#)) and anonymous object initializers ([Anonymous object creation expressions](#)), the definite assignment state is determined by the expansion that these constructs are defined in terms of.

Simple assignment expressions

For an expression $expr$ of the form `w = expr_rhs`:

- The definite assignment state of v before $expr_rhs$ is the same as the definite assignment state of v before $expr$.
- The definite assignment state of v after $expr$ is determined by:
 - If w is the same variable as v , then the definite assignment state of v after $expr$ is definitely assigned.
 - Otherwise, if the assignment occurs within the instance constructor of a struct type, if w is a property access designating an automatically implemented property P on the instance being constructed and v is the hidden backing field of P , then the definite assignment state of v after $expr$ is definitely assigned.
 - Otherwise, the definite assignment state of v after $expr$ is the same as the definite assignment state of v after $expr_rhs$.

&& (conditional AND) expressions

For an expression $expr$ of the form `expr_first && expr_second`:

- The definite assignment state of v before $expr_first$ is the same as the definite assignment state of v before $expr$.
- The definite assignment state of v before $expr_second$ is definitely assigned if the state of v after $expr_first$ is either definitely assigned or "definitely assigned after true expression". Otherwise, it is not definitely assigned.
- The definite assignment state of v after $expr$ is determined by:
 - If $expr_first$ is a constant expression with the value `false`, then the definite assignment state of v after $expr$ is the same as the definite assignment state of v after $expr_first$.
 - Otherwise, if the state of v after $expr_first$ is definitely assigned, then the state of v after $expr$ is definitely assigned.
 - Otherwise, if the state of v after $expr_second$ is definitely assigned, and the state of v after $expr_first$ is "definitely assigned after false expression", then the state of v after $expr$ is definitely assigned.
 - Otherwise, if the state of v after $expr_second$ is definitely assigned or "definitely assigned after true expression", then the state of v after $expr$ is "definitely assigned after true expression".
 - Otherwise, if the state of v after $expr_first$ is "definitely assigned after false expression", and the state of v after $expr_second$ is "definitely assigned after false expression", then the state of v after $expr$ is "definitely assigned after false expression".
 - Otherwise, the state of v after $expr$ is not definitely assigned.

In the example

```

class A
{
    static void F(int x, int y) {
        int i;
        if (x >= 0 && (i = y) >= 0) {
            // i definitely assigned
        }
        else {
            // i not definitely assigned
        }
        // i not definitely assigned
    }
}

```

the variable `i` is considered definitely assigned in one of the embedded statements of an `if` statement but not in the other. In the `if` statement in method `F`, the variable `i` is definitely assigned in the first embedded statement because execution of the expression `(i = y)` always precedes execution of this embedded statement. In contrast, the variable `i` is not definitely assigned in the second embedded statement, since `x >= 0` might have tested false, resulting in the variable `i` being unassigned.

|| (conditional OR) expressions

For an expression `expr` of the form `expr_first || expr_second`:

- The definite assignment state of `v` before `expr_first` is the same as the definite assignment state of `v` before `expr`.
- The definite assignment state of `v` before `expr_second` is definitely assigned if the state of `v` after `expr_first` is either definitely assigned or "definitely assigned after false expression". Otherwise, it is not definitely assigned.
- The definite assignment statement of `v` after `expr` is determined by:
 - If `expr_first` is a constant expression with the value `true`, then the definite assignment state of `v` after `expr` is the same as the definite assignment state of `v` after `expr_first`.
 - Otherwise, if the state of `v` after `expr_first` is definitely assigned, then the state of `v` after `expr` is definitely assigned.
 - Otherwise, if the state of `v` after `expr_second` is definitely assigned, and the state of `v` after `expr_first` is "definitely assigned after true expression", then the state of `v` after `expr` is definitely assigned.
 - Otherwise, if the state of `v` after `expr_second` is definitely assigned or "definitely assigned after false expression", then the state of `v` after `expr` is "definitely assigned after false expression".
 - Otherwise, if the state of `v` after `expr_first` is "definitely assigned after true expression", and the state of `v` after `expr_second` is "definitely assigned after true expression", then the state of `v` after `expr` is "definitely assigned after true expression".
 - Otherwise, the state of `v` after `expr` is not definitely assigned.

In the example

```

class A
{
    static void G(int x, int y) {
        int i;
        if (x >= 0 || (i = y) >= 0) {
            // i not definitely assigned
        }
        else {
            // i definitely assigned
        }
        // i not definitely assigned
    }
}

```

the variable `i` is considered definitely assigned in one of the embedded statements of an `if` statement but not in the other. In the `if` statement in method `G`, the variable `i` is definitely assigned in the second embedded statement because execution of the expression `(i = y)` always precedes execution of this embedded statement. In contrast, the variable `i` is not definitely assigned in the first embedded statement, since `x >= 0` might have tested true, resulting in the variable `i` being unassigned.

! (logical negation) expressions

For an expression `expr` of the form `! expr_operand`:

- The definite assignment state of `v` before `expr_operand` is the same as the definite assignment state of `v` before `expr`.
- The definite assignment state of `v` after `expr` is determined by:
 - If the state of `v` after `*expr_operand` is definitely assigned, then the state of `v` after `expr` is definitely assigned.
 - If the state of `v` after `*expr_operand` is not definitely assigned, then the state of `v` after `expr` is not definitely assigned.
 - If the state of `v` after `*expr_operand` is "definitely assigned after false expression", then the state of `v` after `expr` is "definitely assigned after true expression".
 - If the state of `v` after `*expr_operand` is "definitely assigned after true expression", then the state of `v` after `expr` is "definitely assigned after false expression".

?? (null coalescing) expressions

For an expression `expr` of the form `expr_first ?? expr_second`:

- The definite assignment state of `v` before `expr_first` is the same as the definite assignment state of `v` before `expr`.
- The definite assignment state of `v` before `expr_second` is the same as the definite assignment state of `v` after `expr_first`.
- The definite assignment statement of `v` after `expr` is determined by:
 - If `expr_first` is a constant expression (Constant expressions) with value null, then the state of `v` after `expr` is the same as the state of `v` after `expr_second`.
- Otherwise, the state of `v` after `expr` is the same as the definite assignment state of `v` after `expr_first`.

?: (conditional) expressions

For an expression `expr` of the form `expr_cond ? expr_true : expr_false`:

- The definite assignment state of `v` before `expr_cond` is the same as the state of `v` before `expr`.
- The definite assignment state of `v` before `expr_true` is definitely assigned if and only if one of the following holds:
 - `expr_cond` is a constant expression with the value `false`
 - the state of `v` after `expr_cond` is definitely assigned or "definitely assigned after true expression".

- The definite assignment state of v before $expr_false$ is definitely assigned if and only if one of the following holds:
 - $expr_cond$ is a constant expression with the value `true`
 - the state of v after $expr_cond$ is definitely assigned or "definitely assigned after false expression".
- The definite assignment state of v after $expr$ is determined by:
 - If $expr_cond$ is a constant expression ([Constant expressions](#)) with value `true` then the state of v after $expr$ is the same as the state of v after $expr_true$.
 - Otherwise, if $expr_cond$ is a constant expression ([Constant expressions](#)) with value `false` then the state of v after $expr$ is the same as the state of v after $expr_false$.
 - Otherwise, if the state of v after $expr_true$ is definitely assigned and the state of v after $expr_false$ is definitely assigned, then the state of v after $expr$ is definitely assigned.
 - Otherwise, the state of v after $expr$ is not definitely assigned.

Anonymous functions

For a *lambda_expression* or *anonymous_method_expression* $expr$ with a body (either *block* or *expression*) $body$:

- The definite assignment state of an outer variable v before $body$ is the same as the state of v before $expr$. That is, definite assignment state of outer variables is inherited from the context of the anonymous function.
- The definite assignment state of an outer variable v after $expr$ is the same as the state of v before $expr$.

The example

```
delegate bool Filter(int i);

void F() {
    int max;

    // Error, max is not definitely assigned
    Filter f = (int n) => n < max;

    max = 5;
    DoWork(f);
}
```

generates a compile-time error since `max` is not definitely assigned where the anonymous function is declared.

The example

```
delegate void D();

void F() {
    int n;
    D d = () => { n = 1; };

    d();

    // Error, n is not definitely assigned
    Console.WriteLine(n);
}
```

also generates a compile-time error since the assignment to `n` in the anonymous function has no effect on the definite assignment state of `n` outside the anonymous function.

Variable references

A *variable_reference* is an *expression* that is classified as a variable. A *variable_reference* denotes a storage location that can be accessed both to fetch the current value and to store a new value.

```
variable_reference  
    : expression  
    ;
```

In C and C++, a *variable_reference* is known as an *lvalue*.

Atomicity of variable references

Reads and writes of the following data types are atomic: `bool`, `char`, `byte`, `sbyte`, `short`, `ushort`, `uint`, `int`, `float`, and reference types. In addition, reads and writes of enum types with an underlying type in the previous list are also atomic. Reads and writes of other types, including `long`, `ulong`, `double`, and `decimal`, as well as user-defined types, are not guaranteed to be atomic. Aside from the library functions designed for that purpose, there is no guarantee of atomic read-modify-write, such as in the case of increment or decrement.

Conversions

12/28/2021 • 47 minutes to read • [Edit Online](#)

A **conversion** enables an expression to be treated as being of a particular type. A conversion may cause an expression of a given type to be treated as having a different type, or it may cause an expression without a type to get a type. Conversions can be *implicit* or *explicit*, and this determines whether an explicit cast is required. For instance, the conversion from type `int` to type `long` is implicit, so expressions of type `int` can implicitly be treated as type `long`. The opposite conversion, from type `long` to type `int`, is explicit and so an explicit cast is required.

```
int a = 123;
long b = a;      // implicit conversion from int to long
int c = (int) b; // explicit conversion from long to int
```

Some conversions are defined by the language. Programs may also define their own conversions ([User-defined conversions](#)).

Implicit conversions

The following conversions are classified as implicit conversions:

- Identity conversions
- Implicit numeric conversions
- Implicit enumeration conversions
- Implicit interpolated string conversions
- Implicit nullable conversions
- Null literal conversions
- Implicit reference conversions
- Boxing conversions
- Implicit dynamic conversions
- Implicit constant expression conversions
- User-defined implicit conversions
- Anonymous function conversions
- Method group conversions

Implicit conversions can occur in a variety of situations, including function member invocations ([Compile-time checking of dynamic overload resolution](#)), cast expressions ([Cast expressions](#)), and assignments ([Assignment operators](#)).

The pre-defined implicit conversions always succeed and never cause exceptions to be thrown. Properly designed user-defined implicit conversions should exhibit these characteristics as well.

For the purposes of conversion, the types `object` and `dynamic` are considered equivalent.

However, dynamic conversions ([Implicit dynamic conversions](#) and [Explicit dynamic conversions](#)) apply only to expressions of type `dynamic` ([The dynamic type](#)).

Identity conversion

An identity conversion converts from any type to the same type. This conversion exists such that an entity that

already has a required type can be said to be convertible to that type.

- Because `object` and `dynamic` are considered equivalent there is an identity conversion between `object` and `dynamic`, and between constructed types that are the same when replacing all occurrences of `dynamic` with `object`.

Implicit numeric conversions

The implicit numeric conversions are:

- From `sbyte` to `short`, `int`, `long`, `float`, `double`, Or `decimal`.
- From `byte` to `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `float`, `double`, Or `decimal`.
- From `short` to `int`, `long`, `float`, `double`, Or `decimal`.
- From `ushort` to `int`, `uint`, `long`, `ulong`, `float`, `double`, Or `decimal`.
- From `int` to `long`, `float`, `double`, Or `decimal`.
- From `uint` to `long`, `ulong`, `float`, `double`, Or `decimal`.
- From `long` to `float`, `double`, Or `decimal`.
- From `ulong` to `float`, `double`, Or `decimal`.
- From `char` to `ushort`, `int`, `uint`, `long`, `ulong`, `float`, `double`, Or `decimal`.
- From `float` to `double`.

Conversions from `int`, `uint`, `long`, or `ulong` to `float` and from `long` or `ulong` to `double` may cause a loss of precision, but will never cause a loss of magnitude. The other implicit numeric conversions never lose any information.

There are no implicit conversions to the `char` type, so values of the other integral types do not automatically convert to the `char` type.

Implicit enumeration conversions

An implicit enumeration conversion permits the *decimal_integer_literal* `0` to be converted to any *enum_type* and to any *nullable_type* whose underlying type is an *enum_type*. In the latter case the conversion is evaluated by converting to the underlying *enum_type* and wrapping the result ([Nullable types](#)).

Implicit interpolated string conversions

An implicit interpolated string conversion permits an *interpolated_string_expression* ([Interpolated strings](#)) to be converted to `System.IFormattable` Or `System.FormattableString` (which implements `System.IFormattable`).

When this conversion is applied a string value is not composed from the interpolated string. Instead an instance of `System.FormattableString` is created, as further described in [Interpolated strings](#).

Implicit nullable conversions

Predefined implicit conversions that operate on non-nullable value types can also be used with nullable forms of those types. For each of the predefined implicit identity and numeric conversions that convert from a non-nullable value type `S` to a non-nullable value type `T`, the following implicit nullable conversions exist:

- An implicit conversion from `S?` to `T?`.
- An implicit conversion from `S` to `T?`.

Evaluation of an implicit nullable conversion based on an underlying conversion from `S` to `T` proceeds as follows:

- If the nullable conversion is from `S?` to `T?`:
 - If the source value is null (`HasValue` property is false), the result is the null value of type `T?`.
 - Otherwise, the conversion is evaluated as an unwrapping from `S?` to `S`, followed by the underlying

conversion from `S` to `T`, followed by a wrapping ([Nullable types](#)) from `T` to `T?`.

- If the nullable conversion is from `S` to `T?`, the conversion is evaluated as the underlying conversion from `S` to `T` followed by a wrapping from `T` to `T?`.

Null literal conversions

An implicit conversion exists from the `null` literal to any nullable type. This conversion produces the null value ([Nullable types](#)) of the given nullable type.

Implicit reference conversions

The implicit reference conversions are:

- From any *reference_type* to `object` and `dynamic`.
- From any *class_type* `S` to any *class_type* `T`, provided `S` is derived from `T`.
- From any *class_type* `S` to any *interface_type* `T`, provided `S` implements `T`.
- From any *interface_type* `S` to any *interface_type* `T`, provided `S` is derived from `T`.
- From an *array_type* `S` with an element type `SE` to an *array_type* `T` with an element type `TE`, provided all of the following are true:
 - `S` and `T` differ only in element type. In other words, `S` and `T` have the same number of dimensions.
 - Both `SE` and `TE` are *reference_types*.
 - An implicit reference conversion exists from `SE` to `TE`.
- From any *array_type* to `System.Array` and the interfaces it implements.
- From a single-dimensional array type `S[]` to `System.Collections.Generic.ICollection<T>` and its base interfaces, provided that there is an implicit identity or reference conversion from `S` to `T`.
- From any *delegate_type* to `System.Delegate` and the interfaces it implements.
- From the null literal to any *reference_type*.
- From any *reference_type* to a *reference_type* `T` if it has an implicit identity or reference conversion to a *reference_type* `T0` and `T0` has an identity conversion to `T`.
- From any *reference_type* to an interface or delegate type `T` if it has an implicit identity or reference conversion to an interface or delegate type `T0` and `T0` is variance-convertible ([Variance conversion](#)) to `T`.
- Implicit conversions involving type parameters that are known to be reference types. See [Implicit conversions involving type parameters](#) for more details on implicit conversions involving type parameters.

The implicit reference conversions are those conversions between *reference_types* that can be proven to always succeed, and therefore require no checks at run-time.

Reference conversions, implicit or explicit, never change the referential identity of the object being converted. In other words, while a reference conversion may change the type of the reference, it never changes the type or value of the object being referred to.

Boxing conversions

A boxing conversion permits a *value_type* to be implicitly converted to a reference type. A boxing conversion exists from any *non_nullable_value_type* to `object` and `dynamic`, to `System.ValueType` and to any *interface_type* implemented by the *non_nullable_value_type*. Furthermore an *enum_type* can be converted to the type `System.Enum`.

A boxing conversion exists from a *nullable_type* to a reference type, if and only if a boxing conversion exists from the underlying *non_nullable_value_type* to the reference type.

A value type has a boxing conversion to an interface type `I` if it has a boxing conversion to an interface type `I0` and `I0` has an identity conversion to `I`.

A value type has a boxing conversion to an interface type `I` if it has a boxing conversion to an interface or delegate type `IO` and `IO` is variance-convertible ([Variance conversion](#)) to `I`.

Boxing a value of a *non_nullable_value_type* consists of allocating an object instance and copying the *value_type* value into that instance. A struct can be boxed to the type `System.ValueType`, since that is a base class for all structs ([Inheritance](#)).

Boxing a value of a *nullable_type* proceeds as follows:

- If the source value is null (`HasValue` property is false), the result is a null reference of the target type.
- Otherwise, the result is a reference to a boxed `T` produced by unwrapping and boxing the source value.

Boxing conversions are described further in [Boxing conversions](#).

Implicit dynamic conversions

An implicit dynamic conversion exists from an expression of type `dynamic` to any type `T`. The conversion is dynamically bound ([Dynamic binding](#)), which means that an implicit conversion will be sought at run-time from the run-time type of the expression to `T`. If no conversion is found, a run-time exception is thrown.

Note that this implicit conversion seemingly violates the advice in the beginning of [Implicit conversions](#) that an implicit conversion should never cause an exception. However it is not the conversion itself, but the *finding* of the conversion that causes the exception. The risk of run-time exceptions is inherent in the use of dynamic binding. If dynamic binding of the conversion is not desired, the expression can be first converted to `object`, and then to the desired type.

The following example illustrates implicit dynamic conversions:

```
object o = "object";
dynamic d = "dynamic";

string s1 = o; // Fails at compile-time -- no conversion exists
string s2 = d; // Compiles and succeeds at run-time
int i = d; // Compiles but fails at run-time -- no conversion exists
```

The assignments to `s2` and `i` both employ implicit dynamic conversions, where the binding of the operations is suspended until run-time. At run-time, implicit conversions are sought from the run-time type of `d` -- `string` -- to the target type. A conversion is found to `string` but not to `int`.

Implicit constant expression conversions

An implicit constant expression conversion permits the following conversions:

- A *constant_expression* ([Constant expressions](#)) of type `int` can be converted to type `sbyte`, `byte`, `short`, `ushort`, `uint`, or `ulong`, provided the value of the *constant_expression* is within the range of the destination type.
- A *constant_expression* of type `long` can be converted to type `ulong`, provided the value of the *constant_expression* is not negative.

Implicit conversions involving type parameters

The following implicit conversions exist for a given type parameter `T`:

- From `T` to its effective base class `C`, from `T` to any base class of `C`, and from `T` to any interface implemented by `C`. At run-time, if `T` is a value type, the conversion is executed as a boxing conversion. Otherwise, the conversion is executed as an implicit reference conversion or identity conversion.
- From `T` to an interface type `I` in `T`'s effective interface set and from `T` to any base interface of `I`. At run-time, if `T` is a value type, the conversion is executed as a boxing conversion. Otherwise, the conversion is executed as an implicit reference conversion or identity conversion.

- From `T` to a type parameter `U`, provided `T` depends on `U` ([Type parameter constraints](#)). At run-time, if `U` is a value type, then `T` and `U` are necessarily the same type and no conversion is performed. Otherwise, if `T` is a value type, the conversion is executed as a boxing conversion. Otherwise, the conversion is executed as an implicit reference conversion or identity conversion.
- From the null literal to `T`, provided `T` is known to be a reference type.
- From `T` to a reference type `I` if it has an implicit conversion to a reference type `S0` and `S0` has an identity conversion to `I`. At run-time the conversion is executed the same way as the conversion to `S0`.
- From `T` to an interface type `I` if it has an implicit conversion to an interface or delegate type `I0` and `I0` is variance-convertible to `I` ([Variance conversion](#)). At run-time, if `T` is a value type, the conversion is executed as a boxing conversion. Otherwise, the conversion is executed as an implicit reference conversion or identity conversion.

If `T` is known to be a reference type ([Type parameter constraints](#)), the conversions above are all classified as implicit reference conversions ([Implicit reference conversions](#)). If `T` is not known to be a reference type, the conversions above are classified as boxing conversions ([Boxing conversions](#)).

User-defined implicit conversions

A user-defined implicit conversion consists of an optional standard implicit conversion, followed by execution of a user-defined implicit conversion operator, followed by another optional standard implicit conversion. The exact rules for evaluating user-defined implicit conversions are described in [Processing of user-defined implicit conversions](#).

Anonymous function conversions and method group conversions

Anonymous functions and method groups do not have types in and of themselves, but may be implicitly converted to delegate types or expression tree types. Anonymous function conversions are described in more detail in [Anonymous function conversions](#) and method group conversions in [Method group conversions](#).

Explicit conversions

The following conversions are classified as explicit conversions:

- All implicit conversions.
- Explicit numeric conversions.
- Explicit enumeration conversions.
- Explicit nullable conversions.
- Explicit reference conversions.
- Explicit interface conversions.
- Unboxing conversions.
- Explicit dynamic conversions
- User-defined explicit conversions.

Explicit conversions can occur in cast expressions ([Cast expressions](#)).

The set of explicit conversions includes all implicit conversions. This means that redundant cast expressions are allowed.

The explicit conversions that are not implicit conversions are conversions that cannot be proven to always succeed, conversions that are known to possibly lose information, and conversions across domains of types sufficiently different to merit explicit notation.

Explicit numeric conversions

The explicit numeric conversions are the conversions from a *numeric_type* to another *numeric_type* for which an implicit numeric conversion ([Implicit numeric conversions](#)) does not already exist:

- From `sbyte` to `byte`, `ushort`, `uint`, `ulong`, or `char`.
- From `byte` to `sbyte` and `char`.
- From `short` to `sbyte`, `byte`, `ushort`, `uint`, `ulong`, or `char`.
- From `ushort` to `sbyte`, `byte`, `short`, or `char`.
- From `int` to `sbyte`, `byte`, `short`, `ushort`, `uint`, `ulong`, or `char`.
- From `uint` to `sbyte`, `byte`, `short`, `ushort`, `int`, or `char`.
- From `long` to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `ulong`, or `char`.
- From `ulong` to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, or `char`.
- From `char` to `sbyte`, `byte`, or `short`.
- From `float` to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, or `decimal`.
- From `double` to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, or `decimal`.
- From `decimal` to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, or `double`.

Because the explicit conversions include all implicit and explicit numeric conversions, it is always possible to convert from any *numeric_type* to any other *numeric_type* using a cast expression ([Cast expressions](#)).

The explicit numeric conversions possibly lose information or possibly cause exceptions to be thrown. An explicit numeric conversion is processed as follows:

- For a conversion from an integral type to another integral type, the processing depends on the overflow checking context ([The checked and unchecked operators](#)) in which the conversion takes place:
 - In a `checked` context, the conversion succeeds if the value of the source operand is within the range of the destination type, but throws a `System.OverflowException` if the value of the source operand is outside the range of the destination type.
 - In an `unchecked` context, the conversion always succeeds, and proceeds as follows.
 - If the source type is larger than the destination type, then the source value is truncated by discarding its "extra" most significant bits. The result is then treated as a value of the destination type.
 - If the source type is smaller than the destination type, then the source value is either sign-extended or zero-extended so that it is the same size as the destination type. Sign-extension is used if the source type is signed; zero-extension is used if the source type is unsigned. The result is then treated as a value of the destination type.
 - If the source type is the same size as the destination type, then the source value is treated as a value of the destination type.
- For a conversion from `decimal` to an integral type, the source value is rounded towards zero to the nearest integral value, and this integral value becomes the result of the conversion. If the resulting integral value is outside the range of the destination type, a `System.OverflowException` is thrown.
- For a conversion from `float` or `double` to an integral type, the processing depends on the overflow checking context ([The checked and unchecked operators](#)) in which the conversion takes place:
 - In a `checked` context, the conversion proceeds as follows:
 - If the value of the operand is NaN or infinite, a `System.OverflowException` is thrown.
 - Otherwise, the source operand is rounded towards zero to the nearest integral value. If this integral value is within the range of the destination type then this value is the result of the conversion.
 - Otherwise, a `System.OverflowException` is thrown.
 - In an `unchecked` context, the conversion always succeeds, and proceeds as follows.
 - If the value of the operand is NaN or infinite, the result of the conversion is an unspecified value of the destination type.
 - Otherwise, the source operand is rounded towards zero to the nearest integral value. If this

integral value is within the range of the destination type then this value is the result of the conversion.

- Otherwise, the result of the conversion is an unspecified value of the destination type.
- For a conversion from `double` to `float`, the `double` value is rounded to the nearest `float` value. If the `double` value is too small to represent as a `float`, the result becomes positive zero or negative zero. If the `double` value is too large to represent as a `float`, the result becomes positive infinity or negative infinity. If the `double` value is NaN, the result is also NaN.
- For a conversion from `float` or `double` to `decimal`, the source value is converted to `decimal` representation and rounded to the nearest number after the 28th decimal place if required ([The decimal type](#)). If the source value is too small to represent as a `decimal`, the result becomes zero. If the source value is NaN, infinity, or too large to represent as a `decimal`, a `System.OverflowException` is thrown.
- For a conversion from `decimal` to `float` or `double`, the `decimal` value is rounded to the nearest `double` or `float` value. While this conversion may lose precision, it never causes an exception to be thrown.

Explicit enumeration conversions

The explicit enumeration conversions are:

- From `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, or `decimal` to any *enum_type*.
- From any *enum_type* to `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, or `decimal`.
- From any *enum_type* to any other *enum_type*.

An explicit enumeration conversion between two types is processed by treating any participating *enum_type* as the underlying type of that *enum_type*, and then performing an implicit or explicit numeric conversion between the resulting types. For example, given an *enum_type* `E` with an underlying type of `int`, a conversion from `E` to `byte` is processed as an explicit numeric conversion ([Explicit numeric conversions](#)) from `int` to `byte`, and a conversion from `byte` to `E` is processed as an implicit numeric conversion ([Implicit numeric conversions](#)) from `byte` to `int`.

Explicit nullable conversions

Explicit nullable conversions permit predefined explicit conversions that operate on non-nullable value types to also be used with nullable forms of those types. For each of the predefined explicit conversions that convert from a non-nullable value type `S` to a non-nullable value type `T` ([Identity conversion](#), [Implicit numeric conversions](#), [Implicit enumeration conversions](#), [Explicit numeric conversions](#), and [Explicit enumeration conversions](#)), the following nullable conversions exist:

- An explicit conversion from `S?` to `T?`.
- An explicit conversion from `S` to `T?`.
- An explicit conversion from `S?` to `T`.

Evaluation of a nullable conversion based on an underlying conversion from `S` to `T` proceeds as follows:

- If the nullable conversion is from `S?` to `T?`:
 - If the source value is null (`HasValue` property is false), the result is the null value of type `T?`.
 - Otherwise, the conversion is evaluated as an unwrapping from `S?` to `S`, followed by the underlying conversion from `S` to `T`, followed by a wrapping from `T` to `T?`.
- If the nullable conversion is from `S` to `T?`, the conversion is evaluated as the underlying conversion from `S` to `T` followed by a wrapping from `T` to `T?`.
- If the nullable conversion is from `S?` to `T`, the conversion is evaluated as an unwrapping from `S?` to `S` followed by the underlying conversion from `S` to `T`.

Note that an attempt to unwrap a nullable value will throw an exception if the value is `null`.

Explicit reference conversions

The explicit reference conversions are:

- From `object` and `dynamic` to any other *reference_type*.
- From any *class_type* `S` to any *class_type* `T`, provided `S` is a base class of `T`.
- From any *class_type* `S` to any *interface_type* `T`, provided `S` is not sealed and provided `S` does not implement `T`.
- From any *interface_type* `S` to any *class_type* `T`, provided `T` is not sealed or provided `T` implements `S`.
- From any *interface_type* `S` to any *interface_type* `T`, provided `S` is not derived from `T`.
- From an *array_type* `S` with an element type `SE` to an *array_type* `T` with an element type `TE`, provided all of the following are true:
 - `S` and `T` differ only in element type. In other words, `S` and `T` have the same number of dimensions.
 - Both `SE` and `TE` are *reference_types*.
 - An explicit reference conversion exists from `SE` to `TE`.
- From `System.Array` and the interfaces it implements to any *array_type*.
- From a single-dimensional array type `S[]` to `System.Collections.Generic.ICollection<T>` and its base interfaces, provided that there is an explicit reference conversion from `S` to `T`.
- From `System.Collections.Generic.ICollection<S>` and its base interfaces to a single-dimensional array type `T[]`, provided that there is an explicit identity or reference conversion from `S` to `T`.
- From `System.Delegate` and the interfaces it implements to any *delegate_type*.
- From a reference type to a reference type `T` if it has an explicit reference conversion to a reference type `T0` and `T0` has an identity conversion `T`.
- From a reference type to an interface or delegate type `T` if it has an explicit reference conversion to an interface or delegate type `T0` and either `T0` is variance-convertible to `T` or `T` is variance-convertible to `T0` ([Variance conversion](#)).
- From `D<S1...Sn>` to `D<T1...Tn>` where `D<X1...Xn>` is a generic delegate type, `D<S1...Sn>` is not compatible with or identical to `D<T1...Tn>`, and for each type parameter `xi` of `D` the following holds:
 - If `xi` is invariant, then `Si` is identical to `Ti`.
 - If `xi` is covariant, then there is an implicit or explicit identity or reference conversion from `Si` to `Ti`.
 - If `xi` is contravariant, then `Si` and `Ti` are either identical or both reference types.
- Explicit conversions involving type parameters that are known to be reference types. For more details on explicit conversions involving type parameters, see [Explicit conversions involving type parameters](#).

The explicit reference conversions are those conversions between reference-types that require run-time checks to ensure they are correct.

For an explicit reference conversion to succeed at run-time, the value of the source operand must be `null`, or the actual type of the object referenced by the source operand must be a type that can be converted to the destination type by an implicit reference conversion ([Implicit reference conversions](#)) or boxing conversion ([Boxing conversions](#)). If an explicit reference conversion fails, a `System.InvalidCastException` is thrown.

Reference conversions, implicit or explicit, never change the referential identity of the object being converted. In other words, while a reference conversion may change the type of the reference, it never changes the type or value of the object being referred to.

Unboxing conversions

An unboxing conversion permits a reference type to be explicitly converted to a *value_type*. An unboxing conversion exists from the types `object`, `dynamic` and `System.ValueType` to any *non_nullable_value_type*, and

from any *interface_type* to any *non_nullable_value_type* that implements the *interface_type*. Furthermore type `System.Enum` can be unboxed to any *enum_type*.

An unboxing conversion exists from a reference type to a *nullable_type* if an unboxing conversion exists from the reference type to the underlying *non_nullable_value_type* of the *nullable_type*.

A value type `S` has an unboxing conversion from an interface type `I` if it has an unboxing conversion from an interface type `I0` and `I0` has an identity conversion to `I`.

A value type `S` has an unboxing conversion from an interface type `I` if it has an unboxing conversion from an interface or delegate type `I0` and either `I0` is variance-convertible to `I` or `I` is variance-convertible to `I0` ([Variance conversion](#)).

An unboxing operation consists of first checking that the object instance is a boxed value of the given *value_type*, and then copying the value out of the instance. Unboxing a null reference to a *nullable_type* produces the null value of the *nullable_type*. A struct can be unboxed from the type `System.ValueType`, since that is a base class for all structs ([Inheritance](#)).

Unboxing conversions are described further in [Unboxing conversions](#).

Explicit dynamic conversions

An explicit dynamic conversion exists from an expression of type `dynamic` to any type `T`. The conversion is dynamically bound ([Dynamic binding](#)), which means that an explicit conversion will be sought at run-time from the run-time type of the expression to `T`. If no conversion is found, a run-time exception is thrown.

If dynamic binding of the conversion is not desired, the expression can be first converted to `object`, and then to the desired type.

Assume the following class is defined:

```
class C
{
    int i;

    public C(int i) { this.i = i; }

    public static explicit operator C(string s)
    {
        return new C(int.Parse(s));
    }
}
```

The following example illustrates explicit dynamic conversions:

```
object o = "1";
dynamic d = "2";

var c1 = (C)o; // Compiles, but explicit reference conversion fails
var c2 = (C)d; // Compiles and user defined conversion succeeds
```

The best conversion of `o` to `C` is found at compile-time to be an explicit reference conversion. This fails at run-time, because `"1"` is not in fact a `C`. The conversion of `d` to `C` however, as an explicit dynamic conversion, is suspended to run-time, where a user defined conversion from the run-time type of `d` -- `string` -- to `C` is found, and succeeds.

Explicit conversions involving type parameters

The following explicit conversions exist for a given type parameter `T`:

- From the effective base class `C` of `T` to `T` and from any base class of `C` to `T`. At run-time, if `T` is a value type, the conversion is executed as an unboxing conversion. Otherwise, the conversion is executed as an explicit reference conversion or identity conversion.
- From any interface type to `T`. At run-time, if `T` is a value type, the conversion is executed as an unboxing conversion. Otherwise, the conversion is executed as an explicit reference conversion or identity conversion.
- From `T` to any *interface_type* `I` provided there is not already an implicit conversion from `T` to `I`. At run-time, if `T` is a value type, the conversion is executed as a boxing conversion followed by an explicit reference conversion. Otherwise, the conversion is executed as an explicit reference conversion or identity conversion.
- From a type parameter `U` to `T`, provided `T` depends on `U` ([Type parameter constraints](#)). At run-time, if `U` is a value type, then `T` and `U` are necessarily the same type and no conversion is performed. Otherwise, if `T` is a value type, the conversion is executed as an unboxing conversion. Otherwise, the conversion is executed as an explicit reference conversion or identity conversion.

If `T` is known to be a reference type, the conversions above are all classified as explicit reference conversions ([Explicit reference conversions](#)). If `T` is not known to be a reference type, the conversions above are classified as unboxing conversions ([Unboxing conversions](#)).

The above rules do not permit a direct explicit conversion from an unconstrained type parameter to a non-interface type, which might be surprising. The reason for this rule is to prevent confusion and make the semantics of such conversions clear. For example, consider the following declaration:

```
class X<T>
{
    public static long F(T t) {
        return (long)t;           // Error
    }
}
```

If the direct explicit conversion of `t` to `int` were permitted, one might easily expect that `X<int>.F(7)` would return `7L`. However, it would not, because the standard numeric conversions are only considered when the types are known to be numeric at binding-time. In order to make the semantics clear, the above example must instead be written:

```
class X<T>
{
    public static long F(T t) {
        return (long)(object)t;    // Ok, but will only work when T is long
    }
}
```

This code will now compile but executing `X<int>.F(7)` would then throw an exception at run-time, since a boxed `int` cannot be converted directly to a `long`.

User-defined explicit conversions

A user-defined explicit conversion consists of an optional standard explicit conversion, followed by execution of a user-defined implicit or explicit conversion operator, followed by another optional standard explicit conversion. The exact rules for evaluating user-defined explicit conversions are described in [Processing of user-defined explicit conversions](#).

Standard conversions

The standard conversions are those pre-defined conversions that can occur as part of a user-defined conversion.

Standard implicit conversions

The following implicit conversions are classified as standard implicit conversions:

- Identity conversions ([Identity conversion](#))
- Implicit numeric conversions ([Implicit numeric conversions](#))
- Implicit nullable conversions ([Implicit nullable conversions](#))
- Implicit reference conversions ([Implicit reference conversions](#))
- Boxing conversions ([Boxing conversions](#))
- Implicit constant expression conversions ([Implicit constant expression conversions](#))
- Implicit conversions involving type parameters ([Implicit conversions involving type parameters](#))

The standard implicit conversions specifically exclude user-defined implicit conversions.

Standard explicit conversions

The standard explicit conversions are all standard implicit conversions plus the subset of the explicit conversions for which an opposite standard implicit conversion exists. In other words, if a standard implicit conversion exists from a type `A` to a type `B`, then a standard explicit conversion exists from type `A` to type `B` and from type `B` to type `A`.

User-defined conversions

C# allows the pre-defined implicit and explicit conversions to be augmented by *user-defined conversions*. User-defined conversions are introduced by declaring conversion operators ([Conversion operators](#)) in class and struct types.

Permitted user-defined conversions

C# permits only certain user-defined conversions to be declared. In particular, it is not possible to redefine an already existing implicit or explicit conversion.

For a given source type `S` and target type `T`, if `S` or `T` are nullable types, let `S0` and `T0` refer to their underlying types, otherwise `S0` and `T0` are equal to `S` and `T` respectively. A class or struct is permitted to declare a conversion from a source type `S` to a target type `T` only if all of the following are true:

- `S0` and `T0` are different types.
- Either `S0` or `T0` is the class or struct type in which the operator declaration takes place.
- Neither `S0` nor `T0` is an *interface type*.
- Excluding user-defined conversions, a conversion does not exist from `S` to `T` or from `T` to `S`.

The restrictions that apply to user-defined conversions are discussed further in [Conversion operators](#).

Lifted conversion operators

Given a user-defined conversion operator that converts from a non-nullable value type `S` to a non-nullable value type `T`, a *lifted conversion operator* exists that converts from `S?` to `T?`. This lifted conversion operator performs an unwrapping from `S?` to `S` followed by the user-defined conversion from `S` to `T` followed by a wrapping from `T` to `T?`, except that a null valued `S?` converts directly to a null valued `T?`.

A lifted conversion operator has the same implicit or explicit classification as its underlying user-defined conversion operator. The term "user-defined conversion" applies to the use of both user-defined and lifted conversion operators.

Evaluation of user-defined conversions

A user-defined conversion converts a value from its type, called the *source type*, to another type, called the *target type*. Evaluation of a user-defined conversion centers on finding the *most specific* user-defined conversion operator for the particular source and target types. This determination is broken into several steps:

- Finding the set of classes and structs from which user-defined conversion operators will be considered. This set consists of the source type and its base classes and the target type and its base classes (with the implicit assumptions that only classes and structs can declare user-defined operators, and that non-class types have no base classes). For the purposes of this step, if either the source or target type is a *nullable_type*, their underlying type is used instead.
- From that set of types, determining which user-defined and lifted conversion operators are applicable. For a conversion operator to be applicable, it must be possible to perform a standard conversion ([Standard conversions](#)) from the source type to the operand type of the operator, and it must be possible to perform a standard conversion from the result type of the operator to the target type.
- From the set of applicable user-defined operators, determining which operator is unambiguously the most specific. In general terms, the most specific operator is the operator whose operand type is "closest" to the source type and whose result type is "closest" to the target type. User-defined conversion operators are preferred over lifted conversion operators. The exact rules for establishing the most specific user-defined conversion operator are defined in the following sections.

Once a most specific user-defined conversion operator has been identified, the actual execution of the user-defined conversion involves up to three steps:

- First, if required, performing a standard conversion from the source type to the operand type of the user-defined or lifted conversion operator.
- Next, invoking the user-defined or lifted conversion operator to perform the conversion.
- Finally, if required, performing a standard conversion from the result type of the user-defined or lifted conversion operator to the target type.

Evaluation of a user-defined conversion never involves more than one user-defined or lifted conversion operator. In other words, a conversion from type `S` to type `T` will never first execute a user-defined conversion from `S` to `X` and then execute a user-defined conversion from `X` to `T`.

Exact definitions of evaluation of user-defined implicit or explicit conversions are given in the following sections. The definitions make use of the following terms:

- If a standard implicit conversion ([Standard implicit conversions](#)) exists from a type `A` to a type `B`, and if neither `A` nor `B` are *interface_types*, then `A` is said to be **encompassed by** `B`, and `B` is said to **encompass** `A`.
- The **most encompassing type** in a set of types is the one type that encompasses all other types in the set. If no single type encompasses all other types, then the set has no most encompassing type. In more intuitive terms, the most encompassing type is the "largest" type in the set—the one type to which each of the other types can be implicitly converted.
- The **most encompassed type** in a set of types is the one type that is encompassed by all other types in the set. If no single type is encompassed by all other types, then the set has no most encompassed type. In more intuitive terms, the most encompassed type is the "smallest" type in the set—the one type that can be implicitly converted to each of the other types.

Processing of user-defined implicit conversions

A user-defined implicit conversion from type `S` to type `T` is processed as follows:

- Determine the types `S0` and `T0`. If `S` or `T` are nullable types, `S0` and `T0` are their underlying types, otherwise `S0` and `T0` are equal to `S` and `T` respectively.
- Find the set of types, `D`, from which user-defined conversion operators will be considered. This set consists of `S0` (if `S0` is a class or struct), the base classes of `S0` (if `S0` is a class), and `T0` (if `T0` is a class or struct).
- Find the set of applicable user-defined and lifted conversion operators, `U`. This set consists of the user-defined and lifted implicit conversion operators declared by the classes or structs in `D` that convert from a type encompassing `S` to a type encompassed by `T`. If `U` is empty, the conversion is undefined and a

compile-time error occurs.

- Find the most specific source type, S_x , of the operators in U :
 - If any of the operators in U convert from S , then S_x is S .
 - Otherwise, S_x is the most encompassed type in the combined set of source types of the operators in U . If exactly one most encompassed type cannot be found, then the conversion is ambiguous and a compile-time error occurs.
- Find the most specific target type, T_x , of the operators in U :
 - If any of the operators in U convert to T , then T_x is T .
 - Otherwise, T_x is the most encompassing type in the combined set of target types of the operators in U . If exactly one most encompassing type cannot be found, then the conversion is ambiguous and a compile-time error occurs.
- Find the most specific conversion operator:
 - If U contains exactly one user-defined conversion operator that converts from S_x to T_x , then this is the most specific conversion operator.
 - Otherwise, if U contains exactly one lifted conversion operator that converts from S_x to T_x , then this is the most specific conversion operator.
 - Otherwise, the conversion is ambiguous and a compile-time error occurs.
- Finally, apply the conversion:
 - If S is not S_x , then a standard implicit conversion from S to S_x is performed.
 - The most specific conversion operator is invoked to convert from S_x to T_x .
 - If T_x is not T , then a standard implicit conversion from T_x to T is performed.

Processing of user-defined explicit conversions

A user-defined explicit conversion from type S to type T is processed as follows:

- Determine the types S_0 and T_0 . If S or T are nullable types, S_0 and T_0 are their underlying types, otherwise S_0 and T_0 are equal to S and T respectively.
- Find the set of types, D , from which user-defined conversion operators will be considered. This set consists of S_0 (if S_0 is a class or struct), the base classes of S_0 (if S_0 is a class), T_0 (if T_0 is a class or struct), and the base classes of T_0 (if T_0 is a class).
- Find the set of applicable user-defined and lifted conversion operators, U . This set consists of the user-defined and lifted implicit or explicit conversion operators declared by the classes or structs in D that convert from a type encompassing or encompassed by S to a type encompassing or encompassed by T . If U is empty, the conversion is undefined and a compile-time error occurs.
- Find the most specific source type, S_x , of the operators in U :
 - If any of the operators in U convert from S , then S_x is S .
 - Otherwise, if any of the operators in U convert from types that encompass S , then S_x is the most encompassed type in the combined set of source types of those operators. If no most encompassed type can be found, then the conversion is ambiguous and a compile-time error occurs.
 - Otherwise, S_x is the most encompassing type in the combined set of source types of the operators in U . If exactly one most encompassing type cannot be found, then the conversion is ambiguous and a compile-time error occurs.
- Find the most specific target type, T_x , of the operators in U :
 - If any of the operators in U convert to T , then T_x is T .
 - Otherwise, if any of the operators in U convert to types that are encompassed by T , then T_x is the most encompassing type in the combined set of target types of those operators. If exactly one most encompassing type cannot be found, then the conversion is ambiguous and a compile-time error occurs.

- Otherwise, `TX` is the most encompassed type in the combined set of target types of the operators in `U`. If no most encompassed type can be found, then the conversion is ambiguous and a compile-time error occurs.
- Find the most specific conversion operator:
 - If `U` contains exactly one user-defined conversion operator that converts from `SX` to `TX`, then this is the most specific conversion operator.
 - Otherwise, if `U` contains exactly one lifted conversion operator that converts from `SX` to `TX`, then this is the most specific conversion operator.
 - Otherwise, the conversion is ambiguous and a compile-time error occurs.
- Finally, apply the conversion:
 - If `S` is not `SX`, then a standard explicit conversion from `S` to `SX` is performed.
 - The most specific user-defined conversion operator is invoked to convert from `SX` to `TX`.
 - If `TX` is not `T`, then a standard explicit conversion from `TX` to `T` is performed.

Anonymous function conversions

An *anonymous_method_expression* or *lambda_expression* is classified as an anonymous function ([Anonymous function expressions](#)). The expression does not have a type but can be implicitly converted to a compatible delegate type or expression tree type. Specifically, an anonymous function `F` is compatible with a delegate type `D` provided:

- If `F` contains an *anonymous_function_signature*, then `D` and `F` have the same number of parameters.
- If `F` does not contain an *anonymous_function_signature*, then `D` may have zero or more parameters of any type, as long as no parameter of `D` has the `out` parameter modifier.
- If `F` has an explicitly typed parameter list, each parameter in `D` has the same type and modifiers as the corresponding parameter in `F`.
- If `F` has an implicitly typed parameter list, `D` has no `ref` or `out` parameters.
- If the body of `F` is an expression, and either `D` has a `void` return type or `F` is `async` and `D` has the return type `Task`, then when each parameter of `F` is given the type of the corresponding parameter in `D`, the body of `F` is a valid expression (wrt [Expressions](#)) that would be permitted as a *statement_expression* ([Expression statements](#)).
- If the body of `F` is a statement block, and either `D` has a `void` return type or `F` is `async` and `D` has the return type `Task`, then when each parameter of `F` is given the type of the corresponding parameter in `D`, the body of `F` is a valid statement block (wrt [Blocks](#)) in which no `return` statement specifies an expression.
- If the body of `F` is an expression, and *either* `F` is non-`async` and `D` has a non-void return type `T`, *or* `F` is `async` and `D` has a return type `Task<T>`, then when each parameter of `F` is given the type of the corresponding parameter in `D`, the body of `F` is a valid expression (wrt [Expressions](#)) that is implicitly convertible to `T`.
- If the body of `F` is a statement block, and *either* `F` is non-`async` and `D` has a non-void return type `T`, *or* `F` is `async` and `D` has a return type `Task<T>`, then when each parameter of `F` is given the type of the corresponding parameter in `D`, the body of `F` is a valid statement block (wrt [Blocks](#)) with a non-reachable end point in which each `return` statement specifies an expression that is implicitly convertible to `T`.

For the purpose of brevity, this section uses the short form for the task types `Task` and `Task<T>` ([Async functions](#)).

A lambda expression `F` is compatible with an expression tree type `Expression<D>` if `F` is compatible with the delegate type `D`. Note that this does not apply to anonymous methods, only lambda expressions.

Certain lambda expressions cannot be converted to expression tree types: Even though the conversion *exists*, it fails at compile-time. This is the case if the lambda expression:

- Has a *block* body
- Contains simple or compound assignment operators
- Contains a dynamically bound expression
- Is *async*

The examples that follow use a generic delegate type `Func<A,R>` which represents a function that takes an argument of type `A` and returns a value of type `R`:

```
delegate R Func<A,R>(A arg);
```

In the assignments

```
Func<int,int> f1 = x => x + 1;           // Ok
Func<int,double> f2 = x => x + 1;       // Ok
Func<double,int> f3 = x => x + 1;       // Error
Func<int, Task<int>> f4 = async x => x + 1; // Ok
```

the parameter and return types of each anonymous function are determined from the type of the variable to which the anonymous function is assigned.

The first assignment successfully converts the anonymous function to the delegate type `Func<int,int>` because, when `x` is given type `int`, `x+1` is a valid expression that is implicitly convertible to type `int`.

Likewise, the second assignment successfully converts the anonymous function to the delegate type `Func<int,double>` because the result of `x+1` (of type `int`) is implicitly convertible to type `double`.

However, the third assignment is a compile-time error because, when `x` is given type `double`, the result of `x+1` (of type `double`) is not implicitly convertible to type `int`.

The fourth assignment successfully converts the anonymous *async* function to the delegate type `Func<int, Task<int>>` because the result of `x+1` (of type `int`) is implicitly convertible to the result type `int` of the task type `Task<int>`.

Anonymous functions may influence overload resolution, and participate in type inference. See [Function members](#) for further details.

Evaluation of anonymous function conversions to delegate types

Conversion of an anonymous function to a delegate type produces a delegate instance which references the anonymous function and the (possibly empty) set of captured outer variables that are active at the time of the evaluation. When the delegate is invoked, the body of the anonymous function is executed. The code in the body is executed using the set of captured outer variables referenced by the delegate.

The invocation list of a delegate produced from an anonymous function contains a single entry. The exact target object and target method of the delegate are unspecified. In particular, it is unspecified whether the target object of the delegate is `null`, the `this` value of the enclosing function member, or some other object.

Conversions of semantically identical anonymous functions with the same (possibly empty) set of captured outer variable instances to the same delegate types are permitted (but not required) to return the same delegate instance. The term *semantically identical* is used here to mean that execution of the anonymous functions will, in all cases, produce the same effects given the same arguments. This rule permits code such as the following to be optimized.

```

delegate double Function(double x);

class Test
{
    static double[] Apply(double[] a, Function f) {
        double[] result = new double[a.Length];
        for (int i = 0; i < a.Length; i++) result[i] = f(a[i]);
        return result;
    }

    static void F(double[] a, double[] b) {
        a = Apply(a, (double x) => Math.Sin(x));
        b = Apply(b, (double y) => Math.Sin(y));
        ...
    }
}

```

Since the two anonymous function delegates have the same (empty) set of captured outer variables, and since the anonymous functions are semantically identical, the compiler is permitted to have the delegates refer to the same target method. Indeed, the compiler is permitted to return the very same delegate instance from both anonymous function expressions.

Evaluation of anonymous function conversions to expression tree types

Conversion of an anonymous function to an expression tree type produces an expression tree ([Expression tree types](#)). More precisely, evaluation of the anonymous function conversion leads to the construction of an object structure that represents the structure of the anonymous function itself. The precise structure of the expression tree, as well as the exact process for creating it, are implementation defined.

Implementation example

This section describes a possible implementation of anonymous function conversions in terms of other C# constructs. The implementation described here is based on the same principles used by the Microsoft C# compiler, but it is by no means a mandated implementation, nor is it the only one possible. It only briefly mentions conversions to expression trees, as their exact semantics are outside the scope of this specification.

The remainder of this section gives several examples of code that contains anonymous functions with different characteristics. For each example, a corresponding translation to code that uses only other C# constructs is provided. In the examples, the identifier `D` is assumed to represent the following delegate type:

```

public delegate void D();

```

The simplest form of an anonymous function is one that captures no outer variables:

```

class Test
{
    static void F() {
        D d = () => { Console.WriteLine("test"); };
    }
}

```

This can be translated to a delegate instantiation that references a compiler generated static method in which the code of the anonymous function is placed:

```
class Test
{
    static void F() {
        D d = new D(__Method1);
    }

    static void __Method1() {
        Console.WriteLine("test");
    }
}
```

In the following example, the anonymous function references instance members of `this`:

```
class Test
{
    int x;

    void F() {
        D d = () => { Console.WriteLine(x); };
    }
}
```

This can be translated to a compiler generated instance method containing the code of the anonymous function:

```
class Test
{
    int x;

    void F() {
        D d = new D(__Method1);
    }

    void __Method1() {
        Console.WriteLine(x);
    }
}
```

In this example, the anonymous function captures a local variable:

```
class Test
{
    void F() {
        int y = 123;
        D d = () => { Console.WriteLine(y); };
    }
}
```

The lifetime of the local variable must now be extended to at least the lifetime of the anonymous function delegate. This can be achieved by "hoisting" the local variable into a field of a compiler generated class. Instantiation of the local variable ([Instantiation of local variables](#)) then corresponds to creating an instance of the compiler generated class, and accessing the local variable corresponds to accessing a field in the instance of the compiler generated class. Furthermore, the anonymous function becomes an instance method of the compiler generated class:

```

class Test
{
    void F() {
        __Locals1 __locals1 = new __Locals1();
        __locals1.y = 123;
        D d = new D(__locals1.__Method1);
    }

    class __Locals1
    {
        public int y;

        public void __Method1() {
            Console.WriteLine(y);
        }
    }
}

```

Finally, the following anonymous function captures `this` as well as two local variables with different lifetimes:

```

class Test
{
    int x;

    void F() {
        int y = 123;
        for (int i = 0; i < 10; i++) {
            int z = i * 2;
            D d = () => { Console.WriteLine(x + y + z); };
        }
    }
}

```

Here, a compiler generated class is created for each statement block in which locals are captured such that the locals in the different blocks can have independent lifetimes. An instance of `__Locals2`, the compiler generated class for the inner statement block, contains the local variable `z` and a field that references an instance of `__Locals1`. An instance of `__Locals1`, the compiler generated class for the outer statement block, contains the local variable `y` and a field that references `this` of the enclosing function member. With these data structures it is possible to reach all captured outer variables through an instance of `__Local2`, and the code of the anonymous function can thus be implemented as an instance method of that class.

```

class Test
{
    void F() {
        __Locals1 __locals1 = new __Locals1();
        __locals1.__this = this;
        __locals1.y = 123;
        for (int i = 0; i < 10; i++) {
            __Locals2 __locals2 = new __Locals2();
            __locals2.__locals1 = __locals1;
            __locals2.z = i * 2;
            D d = new D(__locals2.__Method1);
        }
    }

    class __Locals1
    {
        public Test __this;
        public int y;
    }

    class __Locals2
    {
        public __Locals1 __locals1;
        public int z;

        public void __Method1() {
            Console.WriteLine(__locals1.__this.x + __locals1.y + z);
        }
    }
}

```

The same technique applied here to capture local variables can also be used when converting anonymous functions to expression trees: References to the compiler generated objects can be stored in the expression tree, and access to the local variables can be represented as field accesses on these objects. The advantage of this approach is that it allows the "lifted" local variables to be shared between delegates and expression trees.

Method group conversions

An implicit conversion ([Implicit conversions](#)) exists from a method group ([Expression classifications](#)) to a compatible delegate type. Given a delegate type `D` and an expression `E` that is classified as a method group, an implicit conversion exists from `E` to `D` if `E` contains at least one method that is applicable in its normal form ([Applicable function member](#)) to an argument list constructed by use of the parameter types and modifiers of `D`, as described in the following.

The compile-time application of a conversion from a method group `E` to a delegate type `D` is described in the following. Note that the existence of an implicit conversion from `E` to `D` does not guarantee that the compile-time application of the conversion will succeed without error.

- A single method `M` is selected corresponding to a method invocation ([Method invocations](#)) of the form `E(A)`, with the following modifications:
 - The argument list `A` is a list of expressions, each classified as a variable and with the type and modifier (`ref` or `out`) of the corresponding parameter in the *formal_parameter_list* of `D`.
 - The candidate methods considered are only those methods that are applicable in their normal form ([Applicable function member](#)), not those applicable only in their expanded form.
- If the algorithm of [Method invocations](#) produces an error, then a compile-time error occurs. Otherwise the algorithm produces a single best method `M` having the same number of parameters as `D` and the conversion is considered to exist.
- The selected method `M` must be compatible ([Delegate compatibility](#)) with the delegate type `D`, or

otherwise, a compile-time error occurs.

- If the selected method `M` is an instance method, the instance expression associated with `E` determines the target object of the delegate.
- If the selected method `M` is an extension method which is denoted by means of a member access on an instance expression, that instance expression determines the target object of the delegate.
- The result of the conversion is a value of type `D`, namely a newly created delegate that refers to the selected method and target object.
- Note that this process can lead to the creation of a delegate to an extension method, if the algorithm of [Method invocations](#) fails to find an instance method but succeeds in processing the invocation of `E(A)` as an extension method invocation ([Extension method invocations](#)). A delegate thus created captures the extension method as well as its first argument.

The following example demonstrates method group conversions:

```
delegate string D1(object o);

delegate object D2(string s);

delegate object D3();

delegate string D4(object o, params object[] a);

delegate string D5(int i);

class Test
{
    static string F(object o) {...}

    static void G() {
        D1 d1 = F;           // Ok
        D2 d2 = F;           // Ok
        D3 d3 = F;           // Error -- not applicable
        D4 d4 = F;           // Error -- not applicable in normal form
        D5 d5 = F;           // Error -- applicable but not compatible
    }
}
```

The assignment to `d1` implicitly converts the method group `F` to a value of type `D1`.

The assignment to `d2` shows how it is possible to create a delegate to a method that has less derived (contravariant) parameter types and a more derived (covariant) return type.

The assignment to `d3` shows how no conversion exists if the method is not applicable.

The assignment to `d4` shows how the method must be applicable in its normal form.

The assignment to `d5` shows how parameter and return types of the delegate and method are allowed to differ only for reference types.

As with all other implicit and explicit conversions, the cast operator can be used to explicitly perform a method group conversion. Thus, the example

```
object obj = new EventHandler(myDialog.OkClick);
```

could instead be written

```
object obj = (EventHandler)myDialog.OkClick;
```

Method groups may influence overload resolution, and participate in type inference. See [Function members](#) for further details.

The run-time evaluation of a method group conversion proceeds as follows:

- If the method selected at compile-time is an instance method, or it is an extension method which is accessed as an instance method, the target object of the delegate is determined from the instance expression associated with `E`:
 - The instance expression is evaluated. If this evaluation causes an exception, no further steps are executed.
 - If the instance expression is of a *reference_type*, the value computed by the instance expression becomes the target object. If the selected method is an instance method and the target object is `null`, a `System.NullReferenceException` is thrown and no further steps are executed.
 - If the instance expression is of a *value_type*, a boxing operation ([Boxing conversions](#)) is performed to convert the value to an object, and this object becomes the target object.
- Otherwise the selected method is part of a static method call, and the target object of the delegate is `null`.
- A new instance of the delegate type `D` is allocated. If there is not enough memory available to allocate the new instance, a `System.OutOfMemoryException` is thrown and no further steps are executed.
- The new delegate instance is initialized with a reference to the method that was determined at compile-time and a reference to the target object computed above.

Expressions

12/28/2021 • 227 minutes to read • [Edit Online](#)

An expression is a sequence of operators and operands. This chapter defines the syntax, order of evaluation of operands and operators, and meaning of expressions.

Expression classifications

An expression is classified as one of the following:

- A value. Every value has an associated type.
- A variable. Every variable has an associated type, namely the declared type of the variable.
- A namespace. An expression with this classification can only appear as the left hand side of a *member_access* ([Member access](#)). In any other context, an expression classified as a namespace causes a compile-time error.
- A type. An expression with this classification can only appear as the left hand side of a *member_access* ([Member access](#)), or as an operand for the `as` operator ([The as operator](#)), the `is` operator ([The is operator](#)), or the `typeof` operator ([The typeof operator](#)). In any other context, an expression classified as a type causes a compile-time error.
- A method group, which is a set of overloaded methods resulting from a member lookup ([Member lookup](#)). A method group may have an associated instance expression and an associated type argument list. When an instance method is invoked, the result of evaluating the instance expression becomes the instance represented by `this` ([This access](#)). A method group is permitted in an *invocation_expression* ([Invocation expressions](#)), a *delegate_creation_expression* ([Delegate creation expressions](#)) and as the left hand side of an `is` operator, and can be implicitly converted to a compatible delegate type ([Method group conversions](#)). In any other context, an expression classified as a method group causes a compile-time error.
- A null literal. An expression with this classification can be implicitly converted to a reference type or nullable type.
- An anonymous function. An expression with this classification can be implicitly converted to a compatible delegate type or expression tree type.
- A property access. Every property access has an associated type, namely the type of the property. Furthermore, a property access may have an associated instance expression. When an accessor (the `get` or `set` block) of an instance property access is invoked, the result of evaluating the instance expression becomes the instance represented by `this` ([This access](#)).
- An event access. Every event access has an associated type, namely the type of the event. Furthermore, an event access may have an associated instance expression. An event access may appear as the left hand operand of the `+=` and `-=` operators ([Event assignment](#)). In any other context, an expression classified as an event access causes a compile-time error.
- An indexer access. Every indexer access has an associated type, namely the element type of the indexer. Furthermore, an indexer access has an associated instance expression and an associated argument list. When an accessor (the `get` or `set` block) of an indexer access is invoked, the result of evaluating the instance expression becomes the instance represented by `this` ([This access](#)), and the result of evaluating the argument list becomes the parameter list of the invocation.
- Nothing. This occurs when the expression is an invocation of a method with a return type of `void`. An expression classified as nothing is only valid in the context of a *statement_expression* ([Expression statements](#)).

The final result of an expression is never a namespace, type, method group, or event access. Rather, as noted above, these categories of expressions are intermediate constructs that are only permitted in certain contexts.

A property access or indexer access is always reclassified as a value by performing an invocation of the *get accessor* or the *set accessor*. The particular accessor is determined by the context of the property or indexer access: If the access is the target of an assignment, the *set accessor* is invoked to assign a new value ([Simple assignment](#)). Otherwise, the *get accessor* is invoked to obtain the current value ([Values of expressions](#)).

Values of expressions

Most of the constructs that involve an expression ultimately require the expression to denote a **value**. In such cases, if the actual expression denotes a namespace, a type, a method group, or nothing, a compile-time error occurs. However, if the expression denotes a property access, an indexer access, or a variable, the value of the property, indexer, or variable is implicitly substituted:

- The value of a variable is simply the value currently stored in the storage location identified by the variable. A variable must be considered definitely assigned ([Definite assignment](#)) before its value can be obtained, or otherwise a compile-time error occurs.
- The value of a property access expression is obtained by invoking the *get accessor* of the property. If the property has no *get accessor*, a compile-time error occurs. Otherwise, a function member invocation ([Compile-time checking of dynamic overload resolution](#)) is performed, and the result of the invocation becomes the value of the property access expression.
- The value of an indexer access expression is obtained by invoking the *get accessor* of the indexer. If the indexer has no *get accessor*, a compile-time error occurs. Otherwise, a function member invocation ([Compile-time checking of dynamic overload resolution](#)) is performed with the argument list associated with the indexer access expression, and the result of the invocation becomes the value of the indexer access expression.

Static and Dynamic Binding

The process of determining the meaning of an operation based on the type or value of constituent expressions (arguments, operands, receivers) is often referred to as **binding**. For instance the meaning of a method call is determined based on the type of the receiver and arguments. The meaning of an operator is determined based on the type of its operands.

In C# the meaning of an operation is usually determined at compile-time, based on the compile-time type of its constituent expressions. Likewise, if an expression contains an error, the error is detected and reported by the compiler. This approach is known as **static binding**.

However, if an expression is a dynamic expression (i.e. has the type `dynamic`) this indicates that any binding that it participates in should be based on its run-time type (i.e. the actual type of the object it denotes at run-time) rather than the type it has at compile-time. The binding of such an operation is therefore deferred until the time where the operation is to be executed during the running of the program. This is referred to as **dynamic binding**.

When an operation is dynamically bound, little or no checking is performed by the compiler. Instead if the run-time binding fails, errors are reported as exceptions at run-time.

The following operations in C# are subject to binding:

- Member access: `e.M`
- Method invocation: `e.M(e1, ..., eN)`
- Delegate invocation: `e(e1, ..., eN)`
- Element access: `e[e1, ..., eN]`
- Object creation: `new C(e1, ..., eN)`
- Overloaded unary operators: `+`, `-`, `!`, `~`, `++`, `--`, `true`, `false`
- Overloaded binary operators: `+`, `-`, `*`, `/`, `%`, `&`, `&&`, `|`, `||`, `??`, `^`, `<<`, `>>`, `==`, `!=`, `>`, `<`, `>=`, `<=`

- Assignment operators: `=`, `+=`, `-=`, `*=`, `/=`, `%=`, `&=`, `|=`, `^=`, `<<=`, `>>=`
- Implicit and explicit conversions

When no dynamic expressions are involved, C# defaults to static binding, which means that the compile-time types of constituent expressions are used in the selection process. However, when one of the constituent expressions in the operations listed above is a dynamic expression, the operation is instead dynamically bound.

Binding-time

Static binding takes place at compile-time, whereas dynamic binding takes place at run-time. In the following sections, the term *binding-time* refers to either compile-time or run-time, depending on when the binding takes place.

The following example illustrates the notions of static and dynamic binding and of binding-time:

```
object o = 5;
dynamic d = 5;

Console.WriteLine(5); // static binding to Console.WriteLine(int)
Console.WriteLine(o); // static binding to Console.WriteLine(object)
Console.WriteLine(d); // dynamic binding to Console.WriteLine(int)
```

The first two calls are statically bound: the overload of `Console.WriteLine` is picked based on the compile-time type of their argument. Thus, the binding-time is compile-time.

The third call is dynamically bound: the overload of `Console.WriteLine` is picked based on the run-time type of its argument. This happens because the argument is a dynamic expression -- its compile-time type is `dynamic`. Thus, the binding-time for the third call is run-time.

Dynamic binding

The purpose of dynamic binding is to allow C# programs to interact with *dynamic objects*, i.e. objects that do not follow the normal rules of the C# type system. Dynamic objects may be objects from other programming languages with different types systems, or they may be objects that are programmatically setup to implement their own binding semantics for different operations.

The mechanism by which a dynamic object implements its own semantics is implementation defined. A given interface -- again implementation defined -- is implemented by dynamic objects to signal to the C# run-time that they have special semantics. Thus, whenever operations on a dynamic object are dynamically bound, their own binding semantics, rather than those of C# as specified in this document, take over.

While the purpose of dynamic binding is to allow interoperation with dynamic objects, C# allows dynamic binding on all objects, whether they are dynamic or not. This allows for a smoother integration of dynamic objects, as the results of operations on them may not themselves be dynamic objects, but are still of a type unknown to the programmer at compile-time. Also dynamic binding can help eliminate error-prone reflection-based code even when no objects involved are dynamic objects.

The following sections describe for each construct in the language exactly when dynamic binding is applied, what compile time checking -- if any -- is applied, and what the compile-time result and expression classification is.

Types of constituent expressions

When an operation is statically bound, the type of a constituent expression (e.g. a receiver, an argument, an index or an operand) is always considered to be the compile-time type of that expression.

When an operation is dynamically bound, the type of a constituent expression is determined in different ways depending on the compile-time type of the constituent expression:

- A constituent expression of compile-time type `dynamic` is considered to have the type of the actual value that the expression evaluates to at runtime
- A constituent expression whose compile-time type is a type parameter is considered to have the type which the type parameter is bound to at runtime
- Otherwise the constituent expression is considered to have its compile-time type.

Operators

Expressions are constructed from *operands* and *operators*. The operators of an expression indicate which operations to apply to the operands. Examples of operators include `+`, `-`, `*`, `/`, and `new`. Examples of operands include literals, fields, local variables, and expressions.

There are three kinds of operators:

- Unary operators. The unary operators take one operand and use either prefix notation (such as `--x`) or postfix notation (such as `x++`).
- Binary operators. The binary operators take two operands and all use infix notation (such as `x + y`).
- Ternary operator. Only one ternary operator, `?:`, exists; it takes three operands and uses infix notation (`c ? x : y`).

The order of evaluation of operators in an expression is determined by the *precedence* and *associativity* of the operators ([Operator precedence and associativity](#)).

Operands in an expression are evaluated from left to right. For example, in `F(i) + G(i++) * H(i)`, method `F` is called using the old value of `i`, then method `G` is called with the old value of `i`, and, finally, method `H` is called with the new value of `i`. This is separate from and unrelated to operator precedence.

Certain operators can be *overloaded*. Operator overloading permits user-defined operator implementations to be specified for operations where one or both of the operands are of a user-defined class or struct type ([Operator overloading](#)).

Operator precedence and associativity

When an expression contains multiple operators, the *precedence* of the operators controls the order in which the individual operators are evaluated. For example, the expression `x + y * z` is evaluated as `x + (y * z)` because the `*` operator has higher precedence than the binary `+` operator. The precedence of an operator is established by the definition of its associated grammar production. For example, an *additive_expression* consists of a sequence of *multiplicative_expressions* separated by `+` or `-` operators, thus giving the `+` and `-` operators lower precedence than the `*`, `/`, and `%` operators.

The following table summarizes all operators in order of precedence from highest to lowest:

SECTION	CATEGORY	OPERATORS
Primary expressions	Primary	<code>x.y</code> <code>f(x)</code> <code>a[x]</code> <code>x++</code> <code>x--</code> <code>new</code> <code>typeof</code> <code>default</code> <code>checked</code> <code>unchecked</code> <code>delegate</code>
Unary operators	Unary	<code>+</code> <code>-</code> <code>!</code> <code>~</code> <code>++x</code> <code>--x</code> <code>(T)x</code>
Arithmetic operators	Multiplicative	<code>*</code> <code>/</code> <code>%</code>
Arithmetic operators	Additive	<code>+</code> <code>-</code>
Shift operators	Shift	<code><<</code> <code>>></code>

SECTION	CATEGORY	OPERATORS
Relational and type-testing operators	Relational and type testing	< > <= >= is as
Relational and type-testing operators	Equality	== !=
Logical operators	Logical AND	&
Logical operators	Logical XOR	^
Logical operators	Logical OR	
Conditional logical operators	Conditional AND	&&
Conditional logical operators	Conditional OR	
The null coalescing operator	Null coalescing	??
Conditional operator	Conditional	?:
Assignment operators, Anonymous function expressions	Assignment and lambda expression	= *= /= %= += -= <<= >>= &= ^= = =>

When an operand occurs between two operators with the same precedence, the associativity of the operators controls the order in which the operations are performed:

- Except for the assignment operators and the null coalescing operator, all binary operators are **left-associative**, meaning that operations are performed from left to right. For example, `x + y + z` is evaluated as `(x + y) + z`.
- The assignment operators, the null coalescing operator and the conditional operator (`?:`) are **right-associative**, meaning that operations are performed from right to left. For example, `x = y = z` is evaluated as `x = (y = z)`.

Precedence and associativity can be controlled using parentheses. For example, `x + y * z` first multiplies `y` by `z` and then adds the result to `x`, but `(x + y) * z` first adds `x` and `y` and then multiplies the result by `z`.

Operator overloading

All unary and binary operators have predefined implementations that are automatically available in any expression. In addition to the predefined implementations, user-defined implementations can be introduced by including `operator` declarations in classes and structs ([Operators](#)). User-defined operator implementations always take precedence over predefined operator implementations: Only when no applicable user-defined operator implementations exist will the predefined operator implementations be considered, as described in [Unary operator overload resolution](#) and [Binary operator overload resolution](#).

The **overloadable unary operators** are:

```
+ - ! ~ ++ -- true false
```

Although `true` and `false` are not used explicitly in expressions (and therefore are not included in the precedence table in [Operator precedence and associativity](#)), they are considered operators because they are

invoked in several expression contexts: boolean expressions ([Boolean expressions](#)) and expressions involving the conditional ([Conditional operator](#)), and conditional logical operators ([Conditional logical operators](#)).

The *overloadable binary operators* are:

+ - * / % & | ^ << >> == != > < >= <=

Only the operators listed above can be overloaded. In particular, it is not possible to overload member access, method invocation, or the `=`, `&&`, `||`, `??`, `?:`, `=>`, `checked`, `unchecked`, `new`, `typeof`, `default`, `as`, and `is` operators.

When a binary operator is overloaded, the corresponding assignment operator, if any, is also implicitly overloaded. For example, an overload of operator `*` is also an overload of operator `*=`. This is described further in [Compound assignment](#). Note that the assignment operator itself (`=`) cannot be overloaded. An assignment always performs a simple bit-wise copy of a value into a variable.

Cast operations, such as `(T)x`, are overloaded by providing user-defined conversions ([User-defined conversions](#)).

Element access, such as `a[x]`, is not considered an overloadable operator. Instead, user-defined indexing is supported through indexers ([Indexers](#)).

In expressions, operators are referenced using operator notation, and in declarations, operators are referenced using functional notation. The following table shows the relationship between operator and functional notations for unary and binary operators. In the first entry, *op* denotes any overloadable unary prefix operator. In the second entry, *op* denotes the unary postfix `++` and `--` operators. In the third entry, *op* denotes any overloadable binary operator.

OPERATOR NOTATION	FUNCTIONAL NOTATION
<code>op x</code>	<code>operator op(x)</code>
<code>x op</code>	<code>operator op(x)</code>
<code>x op y</code>	<code>operator op(x,y)</code>

User-defined operator declarations always require at least one of the parameters to be of the class or struct type that contains the operator declaration. Thus, it is not possible for a user-defined operator to have the same signature as a predefined operator.

User-defined operator declarations cannot modify the syntax, precedence, or associativity of an operator. For example, the `/` operator is always a binary operator, always has the precedence level specified in [Operator precedence and associativity](#), and is always left-associative.

While it is possible for a user-defined operator to perform any computation it pleases, implementations that produce results other than those that are intuitively expected are strongly discouraged. For example, an implementation of `operator ==` should compare the two operands for equality and return an appropriate `bool` result.

The descriptions of individual operators in [Primary expressions](#) through [Conditional logical operators](#) specify the predefined implementations of the operators and any additional rules that apply to each operator. The descriptions make use of the terms *unary operator overload resolution*, *binary operator overload resolution*, and *numeric promotion*, definitions of which are found in the following sections.

Unary operator overload resolution

An operation of the form `op x` or `x op`, where `op` is an overloadable unary operator, and `x` is an expression of type `T`, is processed as follows:

- The set of candidate user-defined operators provided by `x` for the operation `operator op(x)` is determined using the rules of [Candidate user-defined operators](#).
- If the set of candidate user-defined operators is not empty, then this becomes the set of candidate operators for the operation. Otherwise, the predefined unary `operator op` implementations, including their lifted forms, become the set of candidate operators for the operation. The predefined implementations of a given operator are specified in the description of the operator ([Primary expressions](#) and [Unary operators](#)).
- The overload resolution rules of [Overload resolution](#) are applied to the set of candidate operators to select the best operator with respect to the argument list `(x)`, and this operator becomes the result of the overload resolution process. If overload resolution fails to select a single best operator, a binding-time error occurs.

Binary operator overload resolution

An operation of the form `x op y`, where `op` is an overloadable binary operator, `x` is an expression of type `T`, and `y` is an expression of type `U`, is processed as follows:

- The set of candidate user-defined operators provided by `x` and `y` for the operation `operator op(x,y)` is determined. The set consists of the union of the candidate operators provided by `x` and the candidate operators provided by `y`, each determined using the rules of [Candidate user-defined operators](#). If `x` and `y` are the same type, or if `x` and `y` are derived from a common base type, then shared candidate operators only occur in the combined set once.
- If the set of candidate user-defined operators is not empty, then this becomes the set of candidate operators for the operation. Otherwise, the predefined binary `operator op` implementations, including their lifted forms, become the set of candidate operators for the operation. The predefined implementations of a given operator are specified in the description of the operator ([Arithmetic operators](#) through [Conditional logical operators](#)). For predefined enum and delegate operators, the only operators considered are those defined by an enum or delegate type that is the binding-time type of one of the operands.
- The overload resolution rules of [Overload resolution](#) are applied to the set of candidate operators to select the best operator with respect to the argument list `(x,y)`, and this operator becomes the result of the overload resolution process. If overload resolution fails to select a single best operator, a binding-time error occurs.

Candidate user-defined operators

Given a type `T` and an operation `operator op(A)`, where `op` is an overloadable operator and `A` is an argument list, the set of candidate user-defined operators provided by `T` for `operator op(A)` is determined as follows:

- Determine the type `T0`. If `T` is a nullable type, `T0` is its underlying type, otherwise `T0` is equal to `T`.
- For all `operator op` declarations in `T0` and all lifted forms of such operators, if at least one operator is applicable ([Applicable function member](#)) with respect to the argument list `A`, then the set of candidate operators consists of all such applicable operators in `T0`.
- Otherwise, if `T0` is `object`, the set of candidate operators is empty.
- Otherwise, the set of candidate operators provided by `T0` is the set of candidate operators provided by the direct base class of `T0`, or the effective base class of `T0` if `T0` is a type parameter.

Numeric promotions

Numeric promotion consists of automatically performing certain implicit conversions of the operands of the predefined unary and binary numeric operators. Numeric promotion is not a distinct mechanism, but rather an effect of applying overload resolution to the predefined operators. Numeric promotion specifically does not affect evaluation of user-defined operators, although user-defined operators can be implemented to exhibit

similar effects.

As an example of numeric promotion, consider the predefined implementations of the binary `*` operator:

```
int operator *(int x, int y);
uint operator *(uint x, uint y);
long operator *(long x, long y);
ulong operator *(ulong x, ulong y);
float operator *(float x, float y);
double operator *(double x, double y);
decimal operator *(decimal x, decimal y);
```

When overload resolution rules ([Overload resolution](#)) are applied to this set of operators, the effect is to select the first of the operators for which implicit conversions exist from the operand types. For example, for the operation `b * s`, where `b` is a `byte` and `s` is a `short`, overload resolution selects `operator *(int,int)` as the best operator. Thus, the effect is that `b` and `s` are converted to `int`, and the type of the result is `int`. Likewise, for the operation `i * d`, where `i` is an `int` and `d` is a `double`, overload resolution selects `operator *(double,double)` as the best operator.

Unary numeric promotions

Unary numeric promotion occurs for the operands of the predefined `+`, `-`, and `~` unary operators. Unary numeric promotion simply consists of converting operands of type `sbyte`, `byte`, `short`, `ushort`, or `char` to type `int`. Additionally, for the unary `-` operator, unary numeric promotion converts operands of type `uint` to type `long`.

Binary numeric promotions

Binary numeric promotion occurs for the operands of the predefined `+`, `-`, `*`, `/`, `%`, `&`, `|`, `^`, `==`, `!=`, `>`, `<`, `>=`, and `<=` binary operators. Binary numeric promotion implicitly converts both operands to a common type which, in case of the non-relational operators, also becomes the result type of the operation. Binary numeric promotion consists of applying the following rules, in the order they appear here:

- If either operand is of type `decimal`, the other operand is converted to type `decimal`, or a binding-time error occurs if the other operand is of type `float` or `double`.
- Otherwise, if either operand is of type `double`, the other operand is converted to type `double`.
- Otherwise, if either operand is of type `float`, the other operand is converted to type `float`.
- Otherwise, if either operand is of type `ulong`, the other operand is converted to type `ulong`, or a binding-time error occurs if the other operand is of type `sbyte`, `short`, `int`, or `long`.
- Otherwise, if either operand is of type `long`, the other operand is converted to type `long`.
- Otherwise, if either operand is of type `uint` and the other operand is of type `sbyte`, `short`, or `int`, both operands are converted to type `long`.
- Otherwise, if either operand is of type `uint`, the other operand is converted to type `uint`.
- Otherwise, both operands are converted to type `int`.

Note that the first rule disallows any operations that mix the `decimal` type with the `double` and `float` types. The rule follows from the fact that there are no implicit conversions between the `decimal` type and the `double` and `float` types.

Also note that it is not possible for an operand to be of type `ulong` when the other operand is of a signed integral type. The reason is that no integral type exists that can represent the full range of `ulong` as well as the signed integral types.

In both of the above cases, a cast expression can be used to explicitly convert one operand to a type that is compatible with the other operand.

In the example

```
decimal AddPercent(decimal x, double percent) {
    return x * (1.0 + percent / 100.0);
}
```

a binding-time error occurs because a `decimal` cannot be multiplied by a `double`. The error is resolved by explicitly converting the second operand to `decimal`, as follows:

```
decimal AddPercent(decimal x, double percent) {
    return x * (decimal)(1.0 + percent / 100.0);
}
```

Lifted operators

Lifted operators permit predefined and user-defined operators that operate on non-nullable value types to also be used with nullable forms of those types. Lifted operators are constructed from predefined and user-defined operators that meet certain requirements, as described in the following:

- For the unary operators

```
+ ++ - -- ! ~
```

a lifted form of an operator exists if the operand and result types are both non-nullable value types. The lifted form is constructed by adding a single `?` modifier to the operand and result types. The lifted operator produces a null value if the operand is null. Otherwise, the lifted operator unwraps the operand, applies the underlying operator, and wraps the result.

- For the binary operators

```
+ - * / % & | ^ << >>
```

a lifted form of an operator exists if the operand and result types are all non-nullable value types. The lifted form is constructed by adding a single `?` modifier to each operand and result type. The lifted operator produces a null value if one or both operands are null (an exception being the `&` and `|` operators of the `bool?` type, as described in [Boolean logical operators](#)). Otherwise, the lifted operator unwraps the operands, applies the underlying operator, and wraps the result.

- For the equality operators

```
== !=
```

a lifted form of an operator exists if the operand types are both non-nullable value types and if the result type is `bool`. The lifted form is constructed by adding a single `?` modifier to each operand type. The lifted operator considers two null values equal, and a null value unequal to any non-null value. If both operands are non-null, the lifted operator unwraps the operands and applies the underlying operator to produce the `bool` result.

- For the relational operators

```
< > <= >=
```

a lifted form of an operator exists if the operand types are both non-nullable value types and if the result type is `bool`. The lifted form is constructed by adding a single `?` modifier to each operand type. The

lifted operator produces the value `false` if one or both operands are null. Otherwise, the lifted operator unwraps the operands and applies the underlying operator to produce the `bool` result.

Member lookup

A member lookup is the process whereby the meaning of a name in the context of a type is determined. A member lookup can occur as part of evaluating a *simple_name* (Simple names) or a *member_access* (Member access) in an expression. If the *simple_name* or *member_access* occurs as the *primary_expression* of an *invocation_expression* (Method invocations), the member is said to be invoked.

If a member is a method or event, or if it is a constant, field or property of either a delegate type (Delegates) or the type `dynamic` (The dynamic type), then the member is said to be *invocable*.

Member lookup considers not only the name of a member but also the number of type parameters the member has and whether the member is accessible. For the purposes of member lookup, generic methods and nested generic types have the number of type parameters indicated in their respective declarations and all other members have zero type parameters.

A member lookup of a name `N` with `K` type parameters in a type `T` is processed as follows:

- First, a set of accessible members named `N` is determined:
 - If `T` is a type parameter, then the set is the union of the sets of accessible members named `N` in each of the types specified as a primary constraint or secondary constraint (Type parameter constraints) for `T`, along with the set of accessible members named `N` in `object`.
 - Otherwise, the set consists of all accessible (Member access) members named `N` in `T`, including inherited members and the accessible members named `N` in `object`. If `T` is a constructed type, the set of members is obtained by substituting type arguments as described in Members of constructed types. Members that include an `override` modifier are excluded from the set.
- Next, if `K` is zero, all nested types whose declarations include type parameters are removed. If `K` is not zero, all members with a different number of type parameters are removed. Note that when `K` is zero, methods having type parameters are not removed, since the type inference process (Type inference) might be able to infer the type arguments.
- Next, if the member is *invoked*, all non-*invocable* members are removed from the set.
- Next, members that are hidden by other members are removed from the set. For every member `S.M` in the set, where `S` is the type in which the member `M` is declared, the following rules are applied:
 - If `M` is a constant, field, property, event, or enumeration member, then all members declared in a base type of `S` are removed from the set.
 - If `M` is a type declaration, then all non-types declared in a base type of `S` are removed from the set, and all type declarations with the same number of type parameters as `M` declared in a base type of `S` are removed from the set.
 - If `M` is a method, then all non-method members declared in a base type of `S` are removed from the set.
- Next, interface members that are hidden by class members are removed from the set. This step only has an effect if `T` is a type parameter and `T` has both an effective base class other than `object` and a non-empty effective interface set (Type parameter constraints). For every member `S.M` in the set, where `S` is the type in which the member `M` is declared, the following rules are applied if `S` is a class declaration other than `object`:
 - If `M` is a constant, field, property, event, enumeration member, or type declaration, then all members declared in an interface declaration are removed from the set.
 - If `M` is a method, then all non-method members declared in an interface declaration are removed from the set, and all methods with the same signature as `M` declared in an interface declaration are removed from the set.

- Finally, having removed hidden members, the result of the lookup is determined:
 - If the set consists of a single member that is not a method, then this member is the result of the lookup.
 - Otherwise, if the set contains only methods, then this group of methods is the result of the lookup.
 - Otherwise, the lookup is ambiguous, and a binding-time error occurs.

For member lookups in types other than type parameters and interfaces, and member lookups in interfaces that are strictly single-inheritance (each interface in the inheritance chain has exactly zero or one direct base interface), the effect of the lookup rules is simply that derived members hide base members with the same name or signature. Such single-inheritance lookups are never ambiguous. The ambiguities that can possibly arise from member lookups in multiple-inheritance interfaces are described in [Interface member access](#).

Base types

For purposes of member lookup, a type `T` is considered to have the following base types:

- If `T` is `object`, then `T` has no base type.
- If `T` is an *enum_type*, the base types of `T` are the class types `System.Enum`, `System.ValueType`, and `object`.
- If `T` is a *struct_type*, the base types of `T` are the class types `System.ValueType` and `object`.
- If `T` is a *class_type*, the base types of `T` are the base classes of `T`, including the class type `object`.
- If `T` is an *interface_type*, the base types of `T` are the base interfaces of `T` and the class type `object`.
- If `T` is an *array_type*, the base types of `T` are the class types `System.Array` and `object`.
- If `T` is a *delegate_type*, the base types of `T` are the class types `System.Delegate` and `object`.

Function members

Function members are members that contain executable statements. Function members are always members of types and cannot be members of namespaces. C# defines the following categories of function members:

- Methods
- Properties
- Events
- Indexers
- User-defined operators
- Instance constructors
- Static constructors
- Destructors

Except for destructors and static constructors (which cannot be invoked explicitly), the statements contained in function members are executed through function member invocations. The actual syntax for writing a function member invocation depends on the particular function member category.

The argument list ([Argument lists](#)) of a function member invocation provides actual values or variable references for the parameters of the function member.

Invocations of generic methods may employ type inference to determine the set of type arguments to pass to the method. This process is described in [Type inference](#).

Invocations of methods, indexers, operators and instance constructors employ overload resolution to determine which of a candidate set of function members to invoke. This process is described in [Overload resolution](#).

Once a particular function member has been identified at binding-time, possibly through overload resolution, the actual run-time process of invoking the function member is described in [Compile-time checking of dynamic overload resolution](#).

The following table summarizes the processing that takes place in constructs involving the six categories of function members that can be explicitly invoked. In the table, `e`, `x`, `y`, and `value` indicate expressions classified as variables or values, `T` indicates an expression classified as a type, `F` is the simple name of a method, and `P` is the simple name of a property.

CONSTRUCT	EXAMPLE	DESCRIPTION
Method invocation	<code>F(x,y)</code>	Overload resolution is applied to select the best method <code>F</code> in the containing class or struct. The method is invoked with the argument list <code>(x,y)</code> . If the method is not <code>static</code> , the instance expression is <code>this</code> .
	<code>T.F(x,y)</code>	Overload resolution is applied to select the best method <code>F</code> in the class or struct <code>T</code> . A binding-time error occurs if the method is not <code>static</code> . The method is invoked with the argument list <code>(x,y)</code> .
	<code>e.F(x,y)</code>	Overload resolution is applied to select the best method <code>F</code> in the class, struct, or interface given by the type of <code>e</code> . A binding-time error occurs if the method is <code>static</code> . The method is invoked with the instance expression <code>e</code> and the argument list <code>(x,y)</code> .
Property access	<code>P</code>	The <code>get</code> accessor of the property <code>P</code> in the containing class or struct is invoked. A compile-time error occurs if <code>P</code> is write-only. If <code>P</code> is not <code>static</code> , the instance expression is <code>this</code> .
	<code>P = value</code>	The <code>set</code> accessor of the property <code>P</code> in the containing class or struct is invoked with the argument list <code>(value)</code> . A compile-time error occurs if <code>P</code> is read-only. If <code>P</code> is not <code>static</code> , the instance expression is <code>this</code> .
	<code>T.P</code>	The <code>get</code> accessor of the property <code>P</code> in the class or struct <code>T</code> is invoked. A compile-time error occurs if <code>P</code> is not <code>static</code> or if <code>P</code> is write-only.
	<code>T.P = value</code>	The <code>set</code> accessor of the property <code>P</code> in the class or struct <code>T</code> is invoked with the argument list <code>(value)</code> . A compile-time error occurs if <code>P</code> is not <code>static</code> or if <code>P</code> is read-only.

CONSTRUCT	EXAMPLE	DESCRIPTION
	<code>e.P</code>	The <code>get</code> accessor of the property <code>P</code> in the class, struct, or interface given by the type of <code>e</code> is invoked with the instance expression <code>e</code> . A binding-time error occurs if <code>P</code> is <code>static</code> or if <code>P</code> is write-only.
	<code>e.P = value</code>	The <code>set</code> accessor of the property <code>P</code> in the class, struct, or interface given by the type of <code>e</code> is invoked with the instance expression <code>e</code> and the argument list <code>(value)</code> . A binding-time error occurs if <code>P</code> is <code>static</code> or if <code>P</code> is read-only.
Event access	<code>E += value</code>	The <code>add</code> accessor of the event <code>E</code> in the containing class or struct is invoked. If <code>E</code> is not static, the instance expression is <code>this</code> .
	<code>E -= value</code>	The <code>remove</code> accessor of the event <code>E</code> in the containing class or struct is invoked. If <code>E</code> is not static, the instance expression is <code>this</code> .
	<code>T.E += value</code>	The <code>add</code> accessor of the event <code>E</code> in the class or struct <code>T</code> is invoked. A binding-time error occurs if <code>E</code> is not static.
	<code>T.E -= value</code>	The <code>remove</code> accessor of the event <code>E</code> in the class or struct <code>T</code> is invoked. A binding-time error occurs if <code>E</code> is not static.
	<code>e.E += value</code>	The <code>add</code> accessor of the event <code>E</code> in the class, struct, or interface given by the type of <code>e</code> is invoked with the instance expression <code>e</code> . A binding-time error occurs if <code>E</code> is static.
	<code>e.E -= value</code>	The <code>remove</code> accessor of the event <code>E</code> in the class, struct, or interface given by the type of <code>e</code> is invoked with the instance expression <code>e</code> . A binding-time error occurs if <code>E</code> is static.

CONSTRUCT	EXAMPLE	DESCRIPTION
Indexer access	<code>e[x,y]</code>	Overload resolution is applied to select the best indexer in the class, struct, or interface given by the type of <code>e</code> . The <code>get</code> accessor of the indexer is invoked with the instance expression <code>e</code> and the argument list <code>(x,y)</code> . A binding-time error occurs if the indexer is write-only.
	<code>e[x,y] = value</code>	Overload resolution is applied to select the best indexer in the class, struct, or interface given by the type of <code>e</code> . The <code>set</code> accessor of the indexer is invoked with the instance expression <code>e</code> and the argument list <code>(x,y,value)</code> . A binding-time error occurs if the indexer is read-only.
Operator invocation	<code>-x</code>	Overload resolution is applied to select the best unary operator in the class or struct given by the type of <code>x</code> . The selected operator is invoked with the argument list <code>(x)</code> .
	<code>x + y</code>	Overload resolution is applied to select the best binary operator in the classes or structs given by the types of <code>x</code> and <code>y</code> . The selected operator is invoked with the argument list <code>(x,y)</code> .
Instance constructor invocation	<code>new T(x,y)</code>	Overload resolution is applied to select the best instance constructor in the class or struct <code>T</code> . The instance constructor is invoked with the argument list <code>(x,y)</code> .

Argument lists

Every function member and delegate invocation includes an argument list which provides actual values or variable references for the parameters of the function member. The syntax for specifying the argument list of a function member invocation depends on the function member category:

- For instance constructors, methods, indexers and delegates, the arguments are specified as an *argument_list*, as described below. For indexers, when invoking the `set` accessor, the argument list additionally includes the expression specified as the right operand of the assignment operator.
- For properties, the argument list is empty when invoking the `get` accessor, and consists of the expression specified as the right operand of the assignment operator when invoking the `set` accessor.
- For events, the argument list consists of the expression specified as the right operand of the `+=` or `-=` operator.
- For user-defined operators, the argument list consists of the single operand of the unary operator or the two operands of the binary operator.

The arguments of properties ([Properties](#)), events ([Events](#)), and user-defined operators ([Operators](#)) are always passed as value parameters ([Value parameters](#)). The arguments of indexers ([Indexers](#)) are always passed as

value parameters ([Value parameters](#)) or parameter arrays ([Parameter arrays](#)). Reference and output parameters are not supported for these categories of function members.

The arguments of an instance constructor, method, indexer or delegate invocation are specified as an *argument_list*.

```
argument_list
    : argument (',' argument)*
    ;

argument
    : argument_name? argument_value
    ;

argument_name
    : identifier ':'
    ;

argument_value
    : expression
    | 'ref' variable_reference
    | 'out' variable_reference
    ;
```

An *argument_list* consists of one or more *arguments*, separated by commas. Each argument consists of an optional *argument_name* followed by an *argument_value*. An *argument* with an *argument_name* is referred to as a **named argument**, whereas an *argument* without an *argument_name* is a **positional argument**. It is an error for a positional argument to appear after a named argument in an *argument_list*.

The *argument_value* can take one of the following forms:

- An *expression*, indicating that the argument is passed as a value parameter ([Value parameters](#)).
- The keyword `ref` followed by a *variable_reference* ([Variable references](#)), indicating that the argument is passed as a reference parameter ([Reference parameters](#)). A variable must be definitely assigned ([Definite assignment](#)) before it can be passed as a reference parameter. The keyword `out` followed by a *variable_reference* ([Variable references](#)), indicating that the argument is passed as an output parameter ([Output parameters](#)). A variable is considered definitely assigned ([Definite assignment](#)) following a function member invocation in which the variable is passed as an output parameter.

Corresponding parameters

For each argument in an argument list there has to be a corresponding parameter in the function member or delegate being invoked.

The parameter list used in the following is determined as follows:

- For virtual methods and indexers defined in classes, the parameter list is picked from the most specific declaration or override of the function member, starting with the static type of the receiver, and searching through its base classes.
- For interface methods and indexers, the parameter list is picked from the most specific definition of the member, starting with the interface type and searching through the base interfaces. If no unique parameter list is found, a parameter list with inaccessible names and no optional parameters is constructed, so that invocations cannot use named parameters or omit optional arguments.
- For partial methods, the parameter list of the defining partial method declaration is used.
- For all other function members and delegates there is only a single parameter list, which is the one used.

The position of an argument or parameter is defined as the number of arguments or parameters preceding it in the argument list or parameter list.

The corresponding parameters for function member arguments are established as follows:

- Arguments in the *argument_list* of instance constructors, methods, indexers and delegates:
 - A positional argument where a fixed parameter occurs at the same position in the parameter list corresponds to that parameter.
 - A positional argument of a function member with a parameter array invoked in its normal form corresponds to the parameter array, which must occur at the same position in the parameter list.
 - A positional argument of a function member with a parameter array invoked in its expanded form, where no fixed parameter occurs at the same position in the parameter list, corresponds to an element in the parameter array.
 - A named argument corresponds to the parameter of the same name in the parameter list.
 - For indexers, when invoking the `set` accessor, the expression specified as the right operand of the assignment operator corresponds to the implicit `value` parameter of the `set` accessor declaration.
- For properties, when invoking the `get` accessor there are no arguments. When invoking the `set` accessor, the expression specified as the right operand of the assignment operator corresponds to the implicit `value` parameter of the `set` accessor declaration.
- For user-defined unary operators (including conversions), the single operand corresponds to the single parameter of the operator declaration.
- For user-defined binary operators, the left operand corresponds to the first parameter, and the right operand corresponds to the second parameter of the operator declaration.

Run-time evaluation of argument lists

During the run-time processing of a function member invocation ([Compile-time checking of dynamic overload resolution](#)), the expressions or variable references of an argument list are evaluated in order, from left to right, as follows:

- For a value parameter, the argument expression is evaluated and an implicit conversion ([Implicit conversions](#)) to the corresponding parameter type is performed. The resulting value becomes the initial value of the value parameter in the function member invocation.
- For a reference or output parameter, the variable reference is evaluated and the resulting storage location becomes the storage location represented by the parameter in the function member invocation. If the variable reference given as a reference or output parameter is an array element of a *reference_type*, a run-time check is performed to ensure that the element type of the array is identical to the type of the parameter. If this check fails, a `System.ArrayTypeMismatchException` is thrown.

Methods, indexers, and instance constructors may declare their right-most parameter to be a parameter array ([Parameter arrays](#)). Such function members are invoked either in their normal form or in their expanded form depending on which is applicable ([Applicable function member](#)):

- When a function member with a parameter array is invoked in its normal form, the argument given for the parameter array must be a single expression that is implicitly convertible ([Implicit conversions](#)) to the parameter array type. In this case, the parameter array acts precisely like a value parameter.
- When a function member with a parameter array is invoked in its expanded form, the invocation must specify zero or more positional arguments for the parameter array, where each argument is an expression that is implicitly convertible ([Implicit conversions](#)) to the element type of the parameter array. In this case, the invocation creates an instance of the parameter array type with a length corresponding to the number of arguments, initializes the elements of the array instance with the given argument values, and uses the newly created array instance as the actual argument.

The expressions of an argument list are always evaluated in the order they are written. Thus, the example

```

class Test
{
    static void F(int x, int y = -1, int z = -2) {
        System.Console.WriteLine("x = {0}, y = {1}, z = {2}", x, y, z);
    }

    static void Main() {
        int i = 0;
        F(i++, i++, i++);
        F(z: i++, x: i++);
    }
}

```

produces the output

```

x = 0, y = 1, z = 2
x = 4, y = -1, z = 3

```

The array co-variance rules ([Array covariance](#)) permit a value of an array type `A[]` to be a reference to an instance of an array type `B[]`, provided an implicit reference conversion exists from `B` to `A`. Because of these rules, when an array element of a *reference type* is passed as a reference or output parameter, a run-time check is required to ensure that the actual element type of the array is identical to that of the parameter. In the example

```

class Test
{
    static void F(ref object x) {...}

    static void Main() {
        object[] a = new object[10];
        object[] b = new string[10];
        F(ref a[0]);           // Ok
        F(ref b[1]);           // ArrayTypeMismatchException
    }
}

```

the second invocation of `F` causes a `System.ArrayTypeMismatchException` to be thrown because the actual element type of `b` is `string` and not `object`.

When a function member with a parameter array is invoked in its expanded form, the invocation is processed exactly as if an array creation expression with an array initializer ([Array creation expressions](#)) was inserted around the expanded parameters. For example, given the declaration

```

void F(int x, int y, params object[] args);

```

the following invocations of the expanded form of the method

```

F(10, 20);
F(10, 20, 30, 40);
F(10, 20, 1, "hello", 3.0);

```

correspond exactly to

```

F(10, 20, new object[] {});
F(10, 20, new object[] {30, 40});
F(10, 20, new object[] {1, "hello", 3.0});

```

In particular, note that an empty array is created when there are zero arguments given for the parameter array.

When arguments are omitted from a function member with corresponding optional parameters, the default arguments of the function member declaration are implicitly passed. Because these are always constant, their evaluation will not impact the evaluation order of the remaining arguments.

Type inference

When a generic method is called without specifying type arguments, a *type inference* process attempts to infer type arguments for the call. The presence of type inference allows a more convenient syntax to be used for calling a generic method, and allows the programmer to avoid specifying redundant type information. For example, given the method declaration:

```
class Chooser
{
    static Random rand = new Random();

    public static T Choose<T>(T first, T second) {
        return (rand.Next(2) == 0)? first: second;
    }
}
```

it is possible to invoke the `Choose` method without explicitly specifying a type argument:

```
int i = Chooser.Choose(5, 213);           // Calls Choose<int>

string s = Chooser.Choose("foo", "bar");   // Calls Choose<string>
```

Through type inference, the type arguments `int` and `string` are determined from the arguments to the method.

Type inference occurs as part of the binding-time processing of a method invocation ([Method invocations](#)) and takes place before the overload resolution step of the invocation. When a particular method group is specified in a method invocation, and no type arguments are specified as part of the method invocation, type inference is applied to each generic method in the method group. If type inference succeeds, then the inferred type arguments are used to determine the types of arguments for subsequent overload resolution. If overload resolution chooses a generic method as the one to invoke, then the inferred type arguments are used as the actual type arguments for the invocation. If type inference for a particular method fails, that method does not participate in overload resolution. The failure of type inference, in and of itself, does not cause a binding-time error. However, it often leads to a binding-time error when overload resolution then fails to find any applicable methods.

If the supplied number of arguments is different than the number of parameters in the method, then inference immediately fails. Otherwise, assume that the generic method has the following signature:

```
Tr M<X1,...,Xn>(T1 x1, ..., Tm xm)
```

With a method call of the form `M(E1...Em)` the task of type inference is to find unique type arguments `S1...Sn` for each of the type parameters `X1...Xn` so that the call `M<S1...Sn>(E1...Em)` becomes valid.

During the process of inference each type parameter `xi` is either *fixed* to a particular type `si` or *unfixed* with an associated set of *bounds*. Each of the bounds is some type `T`. Initially each type variable `xi` is unfixed with an empty set of bounds.

Type inference takes place in phases. Each phase will try to infer type arguments for more type variables based on the findings of the previous phase. The first phase makes some initial inferences of bounds, whereas the

second phase fixes type variables to specific types and infers further bounds. The second phase may have to be repeated a number of times.

Note: Type inference takes place not only when a generic method is called. Type inference for conversion of method groups is described in [Type inference for conversion of method groups](#) and finding the best common type of a set of expressions is described in [Finding the best common type of a set of expressions](#).

The first phase

For each of the method arguments E_i :

- If E_i is an anonymous function, an *explicit parameter type inference* ([Explicit parameter type inferences](#)) is made from E_i to T_i .
- Otherwise, if E_i has a type U and x_i is a value parameter then a *lower-bound inference* is made from U to T_i .
- Otherwise, if E_i has a type U and x_i is a `ref` or `out` parameter then an *exact inference* is made from U to T_i .
- Otherwise, no inference is made for this argument.

The second phase

The second phase proceeds as follows:

- All *unfixed* type variables x_i which do not *depend on* ([Dependence](#)) any x_j are fixed ([Fixing](#)).
- If no such type variables exist, all *unfixed* type variables x_i are *fixed* for which all of the following hold:
 - There is at least one type variable x_j that depends on x_i
 - x_i has a non-empty set of bounds
- If no such type variables exist and there are still *unfixed* type variables, type inference fails.
- Otherwise, if no further *unfixed* type variables exist, type inference succeeds.
- Otherwise, for all arguments E_i with corresponding parameter type T_i where the *output types* ([Output types](#)) contain *unfixed* type variables x_j but the *input types* ([Input types](#)) do not, an *output type inference* ([Output type inferences](#)) is made from E_i to T_i . Then the second phase is repeated.

Input types

If E is a method group or implicitly typed anonymous function and T is a delegate type or expression tree type then all the parameter types of T are *input types* of E with type T .

Output types

If E is a method group or an anonymous function and T is a delegate type or expression tree type then the return type of T is an *output type* of E with type T .

Dependence

An *unfixed* type variable x_i *depends directly on* an unfixed type variable x_j if for some argument E_k with type T_k x_j occurs in an *input type* of E_k with type T_k and x_i occurs in an *output type* of E_k with type T_k .

x_j *depends on* x_i if x_j *depends directly on* x_i or if x_i *depends directly on* x_k and x_k *depends on* x_j . Thus "depends on" is the transitive but not reflexive closure of "depends directly on".

Output type inferences

An *output type inference* is made from an expression E to a type T in the following way:

- If E is an anonymous function with inferred return type U ([Inferred return type](#)) and T is a delegate type or expression tree type with return type T_b , then a *lower-bound inference* ([Lower-bound inferences](#)) is made from U to T_b .
- Otherwise, if E is a method group and T is a delegate type or expression tree type with parameter types $T_1 \dots T_k$ and return type T_b , and overload resolution of E with the types $T_1 \dots T_k$ yields a single method

with return type U , then a *lower-bound inference* is made from U to T_b .

- Otherwise, if E is an expression with type U , then a *lower-bound inference* is made from U to T .
- Otherwise, no inferences are made.

Explicit parameter type inferences

An *explicit parameter type inference* is made from an expression E to a type T in the following way:

- If E is an explicitly typed anonymous function with parameter types $U_1 \dots U_k$ and T is a delegate type or expression tree type with parameter types $V_1 \dots V_k$ then for each U_i an *exact inference* ([Exact inferences](#)) is made from U_i to the corresponding V_i .

Exact inferences

An *exact inference* from a type U to a type V is made as follows:

- If V is one of the *unfixed* X_i then U is added to the set of exact bounds for X_i .
- Otherwise, sets $V_1 \dots V_k$ and $U_1 \dots U_k$ are determined by checking if any of the following cases apply:
 - V is an array type $V_1[\dots]$ and U is an array type $U_1[\dots]$ of the same rank
 - V is the type $V_1?$ and U is the type $U_1?$
 - V is a constructed type $C\langle V_1 \dots V_k \rangle$ and U is a constructed type $C\langle U_1 \dots U_k \rangle$

If any of these cases apply then an *exact inference* is made from each U_i to the corresponding V_i .

- Otherwise no inferences are made.

Lower-bound inferences

A *lower-bound inference* from a type U to a type V is made as follows:

- If V is one of the *unfixed* X_i then U is added to the set of lower bounds for X_i .
- Otherwise, if V is the type $V_1?$ and U is the type $U_1?$ then a lower bound inference is made from U_1 to V_1 .
- Otherwise, sets $U_1 \dots U_k$ and $V_1 \dots V_k$ are determined by checking if any of the following cases apply:
 - V is an array type $V_1[\dots]$ and U is an array type $U_1[\dots]$ (or a type parameter whose effective base type is $U_1[\dots]$) of the same rank
 - V is one of `IEnumerable<V1>`, `ICollection<V1>` or `IList<V1>` and U is a one-dimensional array type $U_1[]$ (or a type parameter whose effective base type is $U_1[]$)
 - V is a constructed class, struct, interface or delegate type $C\langle V_1 \dots V_k \rangle$ and there is a unique type $C\langle U_1 \dots U_k \rangle$ such that U (or, if U is a type parameter, its effective base class or any member of its effective interface set) is identical to, inherits from (directly or indirectly), or implements (directly or indirectly) $C\langle U_1 \dots U_k \rangle$.

(The "uniqueness" restriction means that in the case interface `C<T> {} class U: C<X>, C<Y> {}`, then no inference is made when inferring from U to $C\langle T \rangle$ because U_1 could be X or Y .)

If any of these cases apply then an inference is made from each U_i to the corresponding V_i as follows:

- If U_i is not known to be a reference type then an *exact inference* is made
- Otherwise, if U is an array type then a *lower-bound inference* is made
- Otherwise, if V is $C\langle V_1 \dots V_k \rangle$ then inference depends on the i -th type parameter of C :
 - If it is covariant then a *lower-bound inference* is made.
 - If it is contravariant then an *upper-bound inference* is made.
 - If it is invariant then an *exact inference* is made.

- Otherwise, no inferences are made.

Upper-bound inferences

An *upper-bound inference* from a type u to a type v is made as follows:

- If v is one of the *unfixed* x_i then u is added to the set of upper bounds for x_i .
- Otherwise, sets $v_1 \dots v_k$ and $u_1 \dots u_k$ are determined by checking if any of the following cases apply:
 - u is an array type $u_1[\dots]$ and v is an array type $v_1[\dots]$ of the same rank
 - u is one of `IEnumerable<Ue>`, `ICollection<Ue>` or `IList<Ue>` and v is a one-dimensional array type $ve[]$
 - u is the type $u_1?$ and v is the type $v_1?$
 - u is constructed class, struct, interface or delegate type $c<u_1 \dots u_k>$ and v is a class, struct, interface or delegate type which is identical to, inherits from (directly or indirectly), or implements (directly or indirectly) a unique type $c<v_1 \dots v_k>$

(The "uniqueness" restriction means that if we have

`interface C<T>{} class V<Z>: C<X<Z>>, C<Y<Z>>{} , then no inference is made when inferring from $c<u_1>$ to $v<Q>$. Inferences are not made from u_1 to either $x<Q>$ or $y<Q>$.)`

If any of these cases apply then an inference is made *from* each u_i *to* the corresponding v_i as follows:

- If u_i is not known to be a reference type then an *exact inference* is made
- Otherwise, if v is an array type then an *upper-bound inference* is made
- Otherwise, if u is $c<u_1 \dots u_k>$ then inference depends on the i -th type parameter of c :
 - If it is covariant then an *upper-bound inference* is made.
 - If it is contravariant then a *lower-bound inference* is made.
 - If it is invariant then an *exact inference* is made.
- Otherwise, no inferences are made.

Fixing

An *unfixed* type variable x_i with a set of bounds is *fixed* as follows:

- The set of *candidate types* u_j starts out as the set of all types in the set of bounds for x_i .
- We then examine each bound for x_i in turn: For each exact bound u of x_i all types u_j which are not identical to u are removed from the candidate set. For each lower bound u of x_i all types u_j to which there is *not* an implicit conversion from u are removed from the candidate set. For each upper bound u of x_i all types u_j from which there is *not* an implicit conversion to u are removed from the candidate set.
- If among the remaining candidate types u_j there is a unique type v from which there is an implicit conversion to all the other candidate types, then x_i is fixed to v .
- Otherwise, type inference fails.

Inferred return type

The inferred return type of an anonymous function F is used during type inference and overload resolution. The inferred return type can only be determined for an anonymous function where all parameter types are known, either because they are explicitly given, provided through an anonymous function conversion or inferred during type inference on an enclosing generic method invocation.

The *inferred result type* is determined as follows:

- If the body of F is an *expression* that has a type, then the inferred result type of F is the type of that expression.

- If the body of `F` is a *block* and the set of expressions in the block's `return` statements has a best common type `T` ([Finding the best common type of a set of expressions](#)), then the inferred result type of `F` is `T`.
- Otherwise, a result type cannot be inferred for `F`.

The *inferred return type* is determined as follows:

- If `F` is `async` and the body of `F` is either an expression classified as nothing ([Expression classifications](#)), or a statement block where no return statements have expressions, the inferred return type is `System.Threading.Tasks.Task`.
- If `F` is `async` and has an inferred result type `T`, the inferred return type is `System.Threading.Tasks.Task<T>`.
- If `F` is non-`async` and has an inferred result type `T`, the inferred return type is `T`.
- Otherwise a return type cannot be inferred for `F`.

As an example of type inference involving anonymous functions, consider the `Select` extension method declared in the `System.Linq.Enumerable` class:

```
namespace System.Linq
{
    public static class Enumerable
    {
        public static IEnumerable<TResult> Select<TSource,TResult>(
            this IEnumerable<TSource> source,
            Func<TSource,TResult> selector)
        {
            foreach (TSource element in source) yield return selector(element);
        }
    }
}
```

Assuming the `System.Linq` namespace was imported with a `using` clause, and given a class `Customer` with a `Name` property of type `string`, the `Select` method can be used to select the names of a list of customers:

```
List<Customer> customers = GetCustomerList();
IEnumerable<string> names = customers.Select(c => c.Name);
```

The extension method invocation ([Extension method invocations](#)) of `Select` is processed by rewriting the invocation to a static method invocation:

```
IEnumerable<string> names = Enumerable.Select(customers, c => c.Name);
```

Since type arguments were not explicitly specified, type inference is used to infer the type arguments. First, the `customers` argument is related to the `source` parameter, inferring `T` to be `Customer`. Then, using the anonymous function type inference process described above, `c` is given type `Customer`, and the expression `c.Name` is related to the return type of the `selector` parameter, inferring `S` to be `string`. Thus, the invocation is equivalent to

```
Sequence.Select<Customer,string>(customers, (Customer c) => c.Name)
```

and the result is of type `IEnumerable<string>`.

The following example demonstrates how anonymous function type inference allows type information to "flow" between arguments in a generic method invocation. Given the method:

```
static Z F<X,Y,Z>(X value, Func<X,Y> f1, Func<Y,Z> f2) {
    return f2(f1(value));
}
```

Type inference for the invocation:

```
double seconds = F("1:15:30", s => TimeSpan.Parse(s), t => t.TotalSeconds);
```

proceeds as follows: First, the argument `"1:15:30"` is related to the `value` parameter, inferring `X` to be `string`. Then, the parameter of the first anonymous function, `s`, is given the inferred type `string`, and the expression `TimeSpan.Parse(s)` is related to the return type of `f1`, inferring `Y` to be `System.TimeSpan`. Finally, the parameter of the second anonymous function, `t`, is given the inferred type `System.TimeSpan`, and the expression `t.TotalSeconds` is related to the return type of `f2`, inferring `Z` to be `double`. Thus, the result of the invocation is of type `double`.

Type inference for conversion of method groups

Similar to calls of generic methods, type inference must also be applied when a method group `M` containing a generic method is converted to a given delegate type `D` ([Method group conversions](#)). Given a method

```
Tr M<X1...Xn>(T1 x1 ... Tm xm)
```

and the method group `M` being assigned to the delegate type `D` the task of type inference is to find type arguments `S1...Sn` so that the expression:

```
M<S1...Sn>
```

becomes compatible ([Delegate declarations](#)) with `D`.

Unlike the type inference algorithm for generic method calls, in this case there are only argument *types*, no argument *expressions*. In particular, there are no anonymous functions and hence no need for multiple phases of inference.

Instead, all `xi` are considered *unfixed*, and a *lower-bound inference* is made *from* each argument type `uj` of `D` to the corresponding parameter type `Tj` of `M`. If for any of the `xi` no bounds were found, type inference fails. Otherwise, all `xi` are *fixed* to corresponding `si`, which are the result of type inference.

Finding the best common type of a set of expressions

In some cases, a common type needs to be inferred for a set of expressions. In particular, the element types of implicitly typed arrays and the return types of anonymous functions with *block* bodies are found in this way.

Intuitively, given a set of expressions `E1...Em` this inference should be equivalent to calling a method

```
Tr M<X>(X x1 ... X xm)
```

with the `Ei` as arguments.

More precisely, the inference starts out with an *unfixed* type variable `x`. *Output type inferences* are then made *from* each `Ei` to `x`. Finally, `x` is *fixed* and, if successful, the resulting type `s` is the resulting best common type for the expressions. If no such `s` exists, the expressions have no best common type.

Overload resolution

Overload resolution is a binding-time mechanism for selecting the best function member to invoke given an

argument list and a set of candidate function members. Overload resolution selects the function member to invoke in the following distinct contexts within C#:

- Invocation of a method named in an *invocation_expression* ([Method invocations](#)).
- Invocation of an instance constructor named in an *object_creation_expression* ([Object creation expressions](#)).
- Invocation of an indexer accessor through an *element_access* ([Element access](#)).
- Invocation of a predefined or user-defined operator referenced in an expression ([Unary operator overload resolution](#) and [Binary operator overload resolution](#)).

Each of these contexts defines the set of candidate function members and the list of arguments in its own unique way, as described in detail in the sections listed above. For example, the set of candidates for a method invocation does not include methods marked `override` ([Member lookup](#)), and methods in a base class are not candidates if any method in a derived class is applicable ([Method invocations](#)).

Once the candidate function members and the argument list have been identified, the selection of the best function member is the same in all cases:

- Given the set of applicable candidate function members, the best function member in that set is located. If the set contains only one function member, then that function member is the best function member. Otherwise, the best function member is the one function member that is better than all other function members with respect to the given argument list, provided that each function member is compared to all other function members using the rules in [Better function member](#). If there is not exactly one function member that is better than all other function members, then the function member invocation is ambiguous and a binding-time error occurs.

The following sections define the exact meanings of the terms *applicable function member* and *better function member*.

Applicable function member

A function member is said to be an *applicable function member* with respect to an argument list `A` when all of the following are true:

- Each argument in `A` corresponds to a parameter in the function member declaration as described in [Corresponding parameters](#), and any parameter to which no argument corresponds is an optional parameter.
- For each argument in `A`, the parameter passing mode of the argument (i.e., value, `ref`, or `out`) is identical to the parameter passing mode of the corresponding parameter, and
 - for a value parameter or a parameter array, an implicit conversion ([Implicit conversions](#)) exists from the argument to the type of the corresponding parameter, or
 - for a `ref` or `out` parameter, the type of the argument is identical to the type of the corresponding parameter. After all, a `ref` or `out` parameter is an alias for the argument passed.

For a function member that includes a parameter array, if the function member is applicable by the above rules, it is said to be applicable in its *normal form*. If a function member that includes a parameter array is not applicable in its normal form, the function member may instead be applicable in its *expanded form*:

- The expanded form is constructed by replacing the parameter array in the function member declaration with zero or more value parameters of the element type of the parameter array such that the number of arguments in the argument list `A` matches the total number of parameters. If `A` has fewer arguments than the number of fixed parameters in the function member declaration, the expanded form of the function member cannot be constructed and is thus not applicable.
- Otherwise, the expanded form is applicable if for each argument in `A` the parameter passing mode of the argument is identical to the parameter passing mode of the corresponding parameter, and
 - for a fixed value parameter or a value parameter created by the expansion, an implicit conversion ([Implicit conversions](#)) exists from the type of the argument to the type of the corresponding parameter, or

- for a `ref` or `out` parameter, the type of the argument is identical to the type of the corresponding parameter.

Better function member

For the purposes of determining the better function member, a stripped-down argument list A is constructed containing just the argument expressions themselves in the order they appear in the original argument list.

Parameter lists for each of the candidate function members are constructed in the following way:

- The expanded form is used if the function member was applicable only in the expanded form.
- Optional parameters with no corresponding arguments are removed from the parameter list
- The parameters are reordered so that they occur at the same position as the corresponding argument in the argument list.

Given an argument list A with a set of argument expressions $\{E_1, E_2, \dots, E_n\}$ and two applicable function members M_p and M_q with parameter types $\{P_1, P_2, \dots, P_n\}$ and $\{Q_1, Q_2, \dots, Q_n\}$, M_p is defined to be a **better function member** than M_q if

- for each argument, the implicit conversion from E_x to Q_x is not better than the implicit conversion from E_x to P_x , and
- for at least one argument, the conversion from E_x to P_x is better than the conversion from E_x to Q_x .

When performing this evaluation, if M_p or M_q is applicable in its expanded form, then P_x or Q_x refers to a parameter in the expanded form of the parameter list.

In case the parameter type sequences $\{P_1, P_2, \dots, P_n\}$ and $\{Q_1, Q_2, \dots, Q_n\}$ are equivalent (i.e. each P_i has an identity conversion to the corresponding Q_i), the following tie-breaking rules are applied, in order, to determine the better function member.

- If M_p is a non-generic method and M_q is a generic method, then M_p is better than M_q .
- Otherwise, if M_p is applicable in its normal form and M_q has a `params` array and is applicable only in its expanded form, then M_p is better than M_q .
- Otherwise, if M_p has more declared parameters than M_q , then M_p is better than M_q . This can occur if both methods have `params` arrays and are applicable only in their expanded forms.
- Otherwise if all parameters of M_p have a corresponding argument whereas default arguments need to be substituted for at least one optional parameter in M_q then M_p is better than M_q .
- Otherwise, if M_p has more specific parameter types than M_q , then M_p is better than M_q . Let $\{R_1, R_2, \dots, R_n\}$ and $\{S_1, S_2, \dots, S_n\}$ represent the uninstantiated and unexpanded parameter types of M_p and M_q . M_p 's parameter types are more specific than M_q 's if, for each parameter, R_x is not less specific than S_x , and, for at least one parameter, R_x is more specific than S_x :
 - A type parameter is less specific than a non-type parameter.
 - Recursively, a constructed type is more specific than another constructed type (with the same number of type arguments) if at least one type argument is more specific and no type argument is less specific than the corresponding type argument in the other.
 - An array type is more specific than another array type (with the same number of dimensions) if the element type of the first is more specific than the element type of the second.
- Otherwise if one member is a non-lifted operator and the other is a lifted operator, the non-lifted one is better.
- Otherwise, neither function member is better.

Better conversion from expression

Given an implicit conversion C_1 that converts from an expression E to a type T_1 , and an implicit conversion C_2 that converts from an expression E to a type T_2 , C_1 is a **better conversion** than C_2 if E does not

exactly match `T2` and at least one of the following holds:

- `E` exactly matches `T1` ([Exactly matching Expression](#))
- `T1` is a better conversion target than `T2` ([Better conversion target](#))

Exactly matching Expression

Given an expression `E` and a type `T`, `E` exactly matches `T` if one of the following holds:

- `E` has a type `S`, and an identity conversion exists from `S` to `T`
- `E` is an anonymous function, `T` is either a delegate type `D` or an expression tree type `Expression<D>` and one of the following holds:
 - An inferred return type `X` exists for `E` in the context of the parameter list of `D` ([Inferred return type](#)), and an identity conversion exists from `X` to the return type of `D`
 - Either `E` is non-async and `D` has a return type `Y` or `E` is async and `D` has a return type `Task<Y>`, and one of the following holds:
 - The body of `E` is an expression that exactly matches `Y`
 - The body of `E` is a statement block where every return statement returns an expression that exactly matches `Y`

Better conversion target

Given two different types `T1` and `T2`, `T1` is a better conversion target than `T2` if no implicit conversion from `T2` to `T1` exists, and at least one of the following holds:

- An implicit conversion from `T1` to `T2` exists
- `T1` is either a delegate type `D1` or an expression tree type `Expression<D1>`, `T2` is either a delegate type `D2` or an expression tree type `Expression<D2>`, `D1` has a return type `S1` and one of the following holds:
 - `D2` is void returning
 - `D2` has a return type `S2`, and `S1` is a better conversion target than `S2`
- `T1` is `Task<S1>`, `T2` is `Task<S2>`, and `S1` is a better conversion target than `S2`
- `T1` is `S1` or `S1?` where `S1` is a signed integral type, and `T2` is `S2` or `S2?` where `S2` is an unsigned integral type. Specifically:
 - `S1` is `sbyte` and `S2` is `byte`, `ushort`, `uint`, or `ulong`
 - `S1` is `short` and `S2` is `ushort`, `uint`, or `ulong`
 - `S1` is `int` and `S2` is `uint`, or `ulong`
 - `S1` is `long` and `S2` is `ulong`

Overloading in generic classes

While signatures as declared must be unique, it is possible that substitution of type arguments results in identical signatures. In such cases, the tie-breaking rules of overload resolution above will pick the most specific member.

The following examples show overloads that are valid and invalid according to this rule:

```

interface I1<T> {...}

interface I2<T> {...}

class G1<U>
{
    int F1(U u);           // Overload resolution for G<int>.F1
    int F1(int i);         // will pick non-generic

    void F2(I1<U> a);       // Valid overload
    void F2(I2<U> a);
}

class G2<U,V>
{
    void F3(U u, V v);      // Valid, but overload resolution for
    void F3(V v, U u);      // G2<int,int>.F3 will fail

    void F4(U u, I1<V> v);  // Valid, but overload resolution for
    void F4(I1<V> v, U u);  // G2<I1<int>,int>.F4 will fail

    void F5(U u1, I1<V> v2); // Valid overload
    void F5(V v1, U u2);

    void F6(ref U u);        // valid overload
    void F6(out V v);
}

```

Compile-time checking of dynamic overload resolution

For most dynamically bound operations the set of possible candidates for resolution is unknown at compile-time. In certain cases, however the candidate set is known at compile-time:

- Static method calls with dynamic arguments
- Instance method calls where the receiver is not a dynamic expression
- Indexer calls where the receiver is not a dynamic expression
- Constructor calls with dynamic arguments

In these cases a limited compile-time check is performed for each candidate to see if any of them could possibly apply at run-time. This check consists of the following steps:

- Partial type inference: Any type argument that does not depend directly or indirectly on an argument of type `dynamic` is inferred using the rules of [Type inference](#). The remaining type arguments are unknown.
- Partial applicability check: Applicability is checked according to [Applicable function member](#), but ignoring parameters whose types are unknown.
- If no candidate passes this test, a compile-time error occurs.

Function member invocation

This section describes the process that takes place at run-time to invoke a particular function member. It is assumed that a binding-time process has already determined the particular member to invoke, possibly by applying overload resolution to a set of candidate function members.

For purposes of describing the invocation process, function members are divided into two categories:

- Static function members. These are instance constructors, static methods, static property accessors, and user-defined operators. Static function members are always non-virtual.
- Instance function members. These are instance methods, instance property accessors, and indexer accessors. Instance function members are either non-virtual or virtual, and are always invoked on a particular instance. The instance is computed by an instance expression, and it becomes accessible within the function member as `this` ([This access](#)).

The run-time processing of a function member invocation consists of the following steps, where `M` is the function member and, if `M` is an instance member, `E` is the instance expression:

- If `M` is a static function member:
 - The argument list is evaluated as described in [Argument lists](#).
 - `M` is invoked.
- If `M` is an instance function member declared in a *value_type*:
 - `E` is evaluated. If this evaluation causes an exception, then no further steps are executed.
 - If `E` is not classified as a variable, then a temporary local variable of `E`'s type is created and the value of `E` is assigned to that variable. `E` is then reclassified as a reference to that temporary local variable. The temporary variable is accessible as `this` within `M`, but not in any other way. Thus, only when `E` is a true variable is it possible for the caller to observe the changes that `M` makes to `this`.
 - The argument list is evaluated as described in [Argument lists](#).
 - `M` is invoked. The variable referenced by `E` becomes the variable referenced by `this`.
- If `M` is an instance function member declared in a *reference_type*:
 - `E` is evaluated. If this evaluation causes an exception, then no further steps are executed.
 - The argument list is evaluated as described in [Argument lists](#).
 - If the type of `E` is a *value_type*, a boxing conversion ([Boxing conversions](#)) is performed to convert `E` to type `object`, and `E` is considered to be of type `object` in the following steps. In this case, `M` could only be a member of `System.Object`.
 - The value of `E` is checked to be valid. If the value of `E` is `null`, a `System.NullReferenceException` is thrown and no further steps are executed.
 - The function member implementation to invoke is determined:
 - If the binding-time type of `E` is an interface, the function member to invoke is the implementation of `M` provided by the run-time type of the instance referenced by `E`. This function member is determined by applying the interface mapping rules ([Interface mapping](#)) to determine the implementation of `M` provided by the run-time type of the instance referenced by `E`.
 - Otherwise, if `M` is a virtual function member, the function member to invoke is the implementation of `M` provided by the run-time type of the instance referenced by `E`. This function member is determined by applying the rules for determining the most derived implementation ([Virtual methods](#)) of `M` with respect to the run-time type of the instance referenced by `E`.
 - Otherwise, `M` is a non-virtual function member, and the function member to invoke is `M` itself.
 - The function member implementation determined in the step above is invoked. The object referenced by `E` becomes the object referenced by `this`.

Invocations on boxed instances

A function member implemented in a *value_type* can be invoked through a boxed instance of that *value_type* in the following situations:

- When the function member is an `override` of a method inherited from type `object` and is invoked through an instance expression of type `object`.
- When the function member is an implementation of an interface function member and is invoked through an instance expression of an *interface_type*.
- When the function member is invoked through a delegate.

In these situations, the boxed instance is considered to contain a variable of the *value_type*, and this variable becomes the variable referenced by `this` within the function member invocation. In particular, this means that

when a function member is invoked on a boxed instance, it is possible for the function member to modify the value contained in the boxed instance.

Primary expressions

Primary expressions include the simplest forms of expressions.

```
primary_expression
: primary_no_array_creation_expression
| array_creation_expression
;

primary_no_array_creation_expression
: literal
| interpolated_string_expression
| simple_name
| parenthesized_expression
| member_access
| invocation_expression
| element_access
| this_access
| base_access
| post_increment_expression
| post_decrement_expression
| object_creation_expression
| delegate_creation_expression
| anonymous_object_creation_expression
| typeof_expression
| checked_expression
| unchecked_expression
| default_value_expression
| nameof_expression
| anonymous_method_expression
| primary_no_array_creation_expression_unsafe
;
```

Primary expressions are divided between *array_creation_expressions* and *primary_no_array_creation_expressions*. Treating array-creation-expression in this way, rather than listing it along with the other simple expression forms, enables the grammar to disallow potentially confusing code such as

```
object o = new int[3][1];
```

which would otherwise be interpreted as

```
object o = (new int[3])[1];
```

Literals

A *primary_expression* that consists of a *literal* ([Literals](#)) is classified as a value.

Interpolated strings

An *interpolated_string_expression* consists of a `$` sign followed by a regular or verbatim string literal, wherein holes, delimited by `{` and `}`, enclose expressions and formatting specifications. An interpolated string expression is the result of an *interpolated_string_literal* that has been broken up into individual tokens, as described in [Interpolated string literals](#).

```

interpolated_string_expression
    : '$' interpolated_regular_string
    | '$' interpolated_verbatim_string
    ;

interpolated_regular_string
    : interpolated_regular_string_whole
    | interpolated_regular_string_start interpolated_regular_string_body interpolated_regular_string_end
    ;

interpolated_regular_string_body
    : interpolation (interpolated_regular_string_mid interpolation)*
    ;

interpolation
    : expression
    | expression ',' constant_expression
    ;

interpolated_verbatim_string
    : interpolated_verbatim_string_whole
    | interpolated_verbatim_string_start interpolated_verbatim_string_body interpolated_verbatim_string_end
    ;

interpolated_verbatim_string_body
    : interpolation (interpolated_verbatim_string_mid interpolation)+
    ;

```

The *constant_expression* in an interpolation must have an implicit conversion to `int`.

An *interpolated_string_expression* is classified as a value. If it is immediately converted to `System.IFormattable` or `System.FormattableString` with an implicit interpolated string conversion ([Implicit interpolated string conversions](#)), the interpolated string expression has that type. Otherwise, it has the type `string`.

If the type of an interpolated string is `System.IFormattable` or `System.FormattableString`, the meaning is a call to `System.Runtime.CompilerServices.FormattableStringFactory.Create`. If the type is `string`, the meaning of the expression is a call to `string.Format`. In both cases, the argument list of the call consists of a format string literal with placeholders for each interpolation, and an argument for each expression corresponding to the placeholders.

The format string literal is constructed as follows, where `N` is the number of interpolations in the *interpolated_string_expression*.

- If an *interpolated_regular_string_whole* or an *interpolated_verbatim_string_whole* follows the `$` sign, then the format string literal is that token.
- Otherwise, the format string literal consists of:
 - First the *interpolated_regular_string_start* or *interpolated_verbatim_string_start*
 - Then for each number `I` from `0` to `N-1`:
 - The decimal representation of `I`
 - Then, if the corresponding *interpolation* has a *constant_expression*, a `,` (comma) followed by the decimal representation of the value of the *constant_expression*
 - Then the *interpolated_regular_string_mid*, *interpolated_regular_string_end*, *interpolated_verbatim_string_mid* or *interpolated_verbatim_string_end* immediately following the corresponding interpolation.

The subsequent arguments are simply the *expressions* from the *interpolations* (if any), in order.

TODO: examples.

Simple names

A *simple_name* consists of an identifier, optionally followed by a type argument list:

```
simple_name
: identifier type_argument_list?
;
```

A *simple_name* is either of the form `I` or of the form `I<A1, ..., Ak>`, where `I` is a single identifier and `<A1, ..., Ak>` is an optional *type_argument_list*. When no *type_argument_list* is specified, consider `K` to be zero. The *simple_name* is evaluated and classified as follows:

- If `K` is zero and the *simple_name* appears within a *block* and if the *block's* (or an enclosing *block's*) local variable declaration space ([Declarations](#)) contains a local variable, parameter or constant with name `I`, then the *simple_name* refers to that local variable, parameter or constant and is classified as a variable or value.
- If `K` is zero and the *simple_name* appears within the body of a generic method declaration and if that declaration includes a type parameter with name `I`, then the *simple_name* refers to that type parameter.
- Otherwise, for each instance type `T` ([The instance type](#)), starting with the instance type of the immediately enclosing type declaration and continuing with the instance type of each enclosing class or struct declaration (if any):
 - If `K` is zero and the declaration of `T` includes a type parameter with name `I`, then the *simple_name* refers to that type parameter.
 - Otherwise, if a member lookup ([Member lookup](#)) of `I` in `T` with `K` type arguments produces a match:
 - If `T` is the instance type of the immediately enclosing class or struct type and the lookup identifies one or more methods, the result is a method group with an associated instance expression of `this`. If a type argument list was specified, it is used in calling a generic method ([Method invocations](#)).
 - Otherwise, if `T` is the instance type of the immediately enclosing class or struct type, if the lookup identifies an instance member, and if the reference occurs within the body of an instance constructor, an instance method, or an instance accessor, the result is the same as a member access ([Member access](#)) of the form `this.I`. This can only happen when `K` is zero.
 - Otherwise, the result is the same as a member access ([Member access](#)) of the form `T.I` or `T.I<A1, ..., Ak>`. In this case, it is a binding-time error for the *simple_name* to refer to an instance member.
- Otherwise, for each namespace `N`, starting with the namespace in which the *simple_name* occurs, continuing with each enclosing namespace (if any), and ending with the global namespace, the following steps are evaluated until an entity is located:
 - If `K` is zero and `I` is the name of a namespace in `N`, then:
 - If the location where the *simple_name* occurs is enclosed by a namespace declaration for `N` and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name `I` with a namespace or type, then the *simple_name* is ambiguous and a compile-time error occurs.
 - Otherwise, the *simple_name* refers to the namespace named `I` in `N`.
 - Otherwise, if `N` contains an accessible type having name `I` and `K` type parameters, then:
 - If `K` is zero and the location where the *simple_name* occurs is enclosed by a namespace declaration for `N` and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name `I` with a namespace or type, then the

simple_name is ambiguous and a compile-time error occurs.

- Otherwise, the *namespace_or_type_name* refers to the type constructed with the given type arguments.
- Otherwise, if the location where the *simple_name* occurs is enclosed by a namespace declaration for **N**:
 - If **K** is zero and the namespace declaration contains an *extern_alias_directive* or *using_alias_directive* that associates the name **I** with an imported namespace or type, then the *simple_name* refers to that namespace or type.
 - Otherwise, if the namespaces and type declarations imported by the *using_namespace_directives* and *using_static_directives* of the namespace declaration contain exactly one accessible type or non-extension static member having name **I** and **K** type parameters, then the *simple_name* refers to that type or member constructed with the given type arguments.
 - Otherwise, if the namespaces and types imported by the *using_namespace_directives* of the namespace declaration contain more than one accessible type or non-extension-method static member having name **I** and **K** type parameters, then the *simple_name* is ambiguous and an error occurs.

Note that this entire step is exactly parallel to the corresponding step in the processing of a *namespace_or_type_name* ([Namespace and type names](#)).

- Otherwise, the *simple_name* is undefined and a compile-time error occurs.

Parenthesized expressions

A *parenthesized_expression* consists of an *expression* enclosed in parentheses.

```
parenthesized_expression
: '(' expression ')'
;
```

A *parenthesized_expression* is evaluated by evaluating the *expression* within the parentheses. If the *expression* within the parentheses denotes a namespace or type, a compile-time error occurs. Otherwise, the result of the *parenthesized_expression* is the result of the evaluation of the contained *expression*.

Member access

A *member_access* consists of a *primary_expression*, a *predefined_type*, or a *qualified_alias_member*, followed by a "." token, followed by an *identifier*, optionally followed by a *type_argument_list*.

```
member_access
: primary_expression '.' identifier type_argument_list?
| predefined_type '.' identifier type_argument_list?
| qualified_alias_member '.' identifier
;

predefined_type
: 'bool' | 'byte' | 'char' | 'decimal' | 'double' | 'float' | 'int' | 'long'
| 'object' | 'sbyte' | 'short' | 'string' | 'uint' | 'ulong' | 'ushort'
;
```

The *qualified_alias_member* production is defined in [Namespace alias qualifiers](#).

A *member_access* is either of the form **E.I** or of the form **E.I<A1, ..., Ak>**, where **E** is a primary-expression, **I** is a single identifier and **<A1, ..., Ak>** is an optional *type_argument_list*. When no *type_argument_list* is specified, consider **K** to be zero.

A *member_access* with a *primary_expression* of type `dynamic` is dynamically bound ([Dynamic binding](#)). In this case the compiler classifies the member access as a property access of type `dynamic`. The rules below to determine the meaning of the *member_access* are then applied at run-time, using the run-time type instead of the compile-time type of the *primary_expression*. If this run-time classification leads to a method group, then the member access must be the *primary_expression* of an *invocation_expression*.

The *member_access* is evaluated and classified as follows:

- If `K` is zero and `E` is a namespace and `E` contains a nested namespace with name `I`, then the result is that namespace.
- Otherwise, if `E` is a namespace and `E` contains an accessible type having name `I` and `K` type parameters, then the result is that type constructed with the given type arguments.
- If `E` is a *predefined_type* or a *primary_expression* classified as a type, if `E` is not a type parameter, and if a member lookup ([Member lookup](#)) of `I` in `E` with `K` type parameters produces a match, then `E.I` is evaluated and classified as follows:
 - If `I` identifies a type, then the result is that type constructed with the given type arguments.
 - If `I` identifies one or more methods, then the result is a method group with no associated instance expression. If a type argument list was specified, it is used in calling a generic method ([Method invocations](#)).
 - If `I` identifies a `static` property, then the result is a property access with no associated instance expression.
 - If `I` identifies a `static` field:
 - If the field is `readonly` and the reference occurs outside the static constructor of the class or struct in which the field is declared, then the result is a value, namely the value of the static field `I` in `E`.
 - Otherwise, the result is a variable, namely the static field `I` in `E`.
 - If `I` identifies a `static` event:
 - If the reference occurs within the class or struct in which the event is declared, and the event was declared without *event_accessor_declarations* ([Events](#)), then `E.I` is processed exactly as if `I` were a static field.
 - Otherwise, the result is an event access with no associated instance expression.
 - If `I` identifies a constant, then the result is a value, namely the value of that constant.
 - If `I` identifies an enumeration member, then the result is a value, namely the value of that enumeration member.
 - Otherwise, `E.I` is an invalid member reference, and a compile-time error occurs.
- If `E` is a property access, indexer access, variable, or value, the type of which is `T`, and a member lookup ([Member lookup](#)) of `I` in `T` with `K` type arguments produces a match, then `E.I` is evaluated and classified as follows:
 - First, if `E` is a property or indexer access, then the value of the property or indexer access is obtained ([Values of expressions](#)) and `E` is reclassified as a value.
 - If `I` identifies one or more methods, then the result is a method group with an associated instance expression of `E`. If a type argument list was specified, it is used in calling a generic method ([Method invocations](#)).
 - If `I` identifies an instance property,
 - If `E` is `this`, `I` identifies an automatically implemented property ([Automatically implemented properties](#)) without a setter, and the reference occurs within an instance constructor for a class or struct type `T`, then the result is a variable, namely the hidden backing field for the auto-property given by `I` in the instance of `T` given by `this`.
 - Otherwise, the result is a property access with an associated instance expression of `E`.

- If `T` is a *class_type* and `I` identifies an instance field of that *class_type*:
 - If the value of `E` is `null`, then a `System.NullReferenceException` is thrown.
 - Otherwise, if the field is `readonly` and the reference occurs outside an instance constructor of the class in which the field is declared, then the result is a value, namely the value of the field `I` in the object referenced by `E`.
 - Otherwise, the result is a variable, namely the field `I` in the object referenced by `E`.
- If `T` is a *struct_type* and `I` identifies an instance field of that *struct_type*:
 - If `E` is a value, or if the field is `readonly` and the reference occurs outside an instance constructor of the struct in which the field is declared, then the result is a value, namely the value of the field `I` in the struct instance given by `E`.
 - Otherwise, the result is a variable, namely the field `I` in the struct instance given by `E`.
- If `I` identifies an instance event:
 - If the reference occurs within the class or struct in which the event is declared, and the event was declared without *event_accessor_declarations* ([Events](#)), and the reference does not occur as the left-hand side of a `+=` or `-=` operator, then `E.I` is processed exactly as if `I` was an instance field.
 - Otherwise, the result is an event access with an associated instance expression of `E`.
- Otherwise, an attempt is made to process `E.I` as an extension method invocation ([Extension method invocations](#)). If this fails, `E.I` is an invalid member reference, and a binding-time error occurs.

Identical simple names and type names

In a member access of the form `E.I`, if `E` is a single identifier, and if the meaning of `E` as a *simple_name* ([Simple names](#)) is a constant, field, property, local variable, or parameter with the same type as the meaning of `E` as a *type_name* ([Namespace and type names](#)), then both possible meanings of `E` are permitted. The two possible meanings of `E.I` are never ambiguous, since `I` must necessarily be a member of the type `E` in both cases. In other words, the rule simply permits access to the static members and nested types of `E` where a compile-time error would otherwise have occurred. For example:

```
struct Color
{
    public static readonly Color White = new Color(...);
    public static readonly Color Black = new Color(...);

    public Color Complement() {...}
}

class A
{
    public Color Color;           // Field Color of type Color

    void F() {
        Color = Color.Black;      // References Color.Black static member
        Color = Color.Complement(); // Invokes Complement() on Color field
    }

    static void G() {
        Color c = Color.White;    // References Color.White static member
    }
}
```

Grammar ambiguities

The productions for *simple_name* ([Simple names](#)) and *member_access* ([Member access](#)) can give rise to ambiguities in the grammar for expressions. For example, the statement:

```
F(G<A,B>(7));
```

could be interpreted as a call to `F` with two arguments, `G < A` and `B > (7)`. Alternatively, it could be interpreted as a call to `F` with one argument, which is a call to a generic method `G` with two type arguments and one regular argument.

If a sequence of tokens can be parsed (in context) as a *simple_name* (Simple names), *member_access* (Member access), or *pointer_member_access* (Pointer member access) ending with a *type_argument_list* (Type arguments), the token immediately following the closing `>` token is examined. If it is one of

```
( ) ] } : ; , . ? == != | ^
```

then the *type_argument_list* is retained as part of the *simple_name*, *member_access* or *pointer_member_access* and any other possible parse of the sequence of tokens is discarded. Otherwise, the *type_argument_list* is not considered to be part of the *simple_name*, *member_access* or *pointer_member_access*, even if there is no other possible parse of the sequence of tokens. Note that these rules are not applied when parsing a *type_argument_list* in a *namespace_or_type_name* (Namespace and type names). The statement

```
F(G<A,B>(7));
```

will, according to this rule, be interpreted as a call to `F` with one argument, which is a call to a generic method `G` with two type arguments and one regular argument. The statements

```
F(G < A, B > 7);  
F(G < A, B >> 7);
```

will each be interpreted as a call to `F` with two arguments. The statement

```
x = F < A > +y;
```

will be interpreted as a less than operator, greater than operator, and unary plus operator, as if the statement had been written `x = (F < A) > (+y)`, instead of as a *simple_name* with a *type_argument_list* followed by a binary plus operator. In the statement

```
x = y is C<T> + z;
```

the tokens `C<T>` are interpreted as a *namespace_or_type_name* with a *type_argument_list*.

Invocation expressions

An *invocation_expression* is used to invoke a method.

```
invocation_expression  
    : primary_expression '(' argument_list? ')'  
    ;
```

An *invocation_expression* is dynamically bound (Dynamic binding) if at least one of the following holds:

- The *primary_expression* has compile-time type `dynamic`.
- At least one argument of the optional *argument_list* has compile-time type `dynamic` and the *primary_expression* does not have a delegate type.

In this case the compiler classifies the *invocation_expression* as a value of type `dynamic`. The rules below to determine the meaning of the *invocation_expression* are then applied at run-time, using the run-time type instead of the compile-time type of those of the *primary_expression* and arguments which have the compile-time type `dynamic`. If the *primary_expression* does not have compile-time type `dynamic`, then the method invocation undergoes a limited compile time check as described in [Compile-time checking of dynamic overload resolution](#).

The *primary_expression* of an *invocation_expression* must be a method group or a value of a *delegate_type*. If the *primary_expression* is a method group, the *invocation_expression* is a method invocation ([Method invocations](#)). If the *primary_expression* is a value of a *delegate_type*, the *invocation_expression* is a delegate invocation ([Delegate invocations](#)). If the *primary_expression* is neither a method group nor a value of a *delegate_type*, a binding-time error occurs.

The optional *argument_list* ([Argument lists](#)) provides values or variable references for the parameters of the method.

The result of evaluating an *invocation_expression* is classified as follows:

- If the *invocation_expression* invokes a method or delegate that returns `void`, the result is nothing. An expression that is classified as nothing is permitted only in the context of a *statement_expression* ([Expression statements](#)) or as the body of a *lambda_expression* ([Anonymous function expressions](#)). Otherwise a binding-time error occurs.
- Otherwise, the result is a value of the type returned by the method or delegate.

Method invocations

For a method invocation, the *primary_expression* of the *invocation_expression* must be a method group. The method group identifies the one method to invoke or the set of overloaded methods from which to choose a specific method to invoke. In the latter case, determination of the specific method to invoke is based on the context provided by the types of the arguments in the *argument_list*.

The binding-time processing of a method invocation of the form `M(A)`, where `M` is a method group (possibly including a *type_argument_list*), and `A` is an optional *argument_list*, consists of the following steps:

- The set of candidate methods for the method invocation is constructed. For each method `F` associated with the method group `M`:
 - If `F` is non-generic, `F` is a candidate when:
 - `M` has no type argument list, and
 - `F` is applicable with respect to `A` ([Applicable function member](#)).
 - If `F` is generic and `M` has no type argument list, `F` is a candidate when:
 - Type inference ([Type inference](#)) succeeds, inferring a list of type arguments for the call, and
 - Once the inferred type arguments are substituted for the corresponding method type parameters, all constructed types in the parameter list of `F` satisfy their constraints ([Satisfying constraints](#)), and the parameter list of `F` is applicable with respect to `A` ([Applicable function member](#)).
 - If `F` is generic and `M` includes a type argument list, `F` is a candidate when:
 - `F` has the same number of method type parameters as were supplied in the type argument list, and
 - Once the type arguments are substituted for the corresponding method type parameters, all constructed types in the parameter list of `F` satisfy their constraints ([Satisfying constraints](#)), and the parameter list of `F` is applicable with respect to `A` ([Applicable function member](#)).
- The set of candidate methods is reduced to contain only methods from the most derived types: For each method `C.F` in the set, where `C` is the type in which the method `F` is declared, all methods declared in a base type of `C` are removed from the set. Furthermore, if `C` is a class type other than `object`, all methods

declared in an interface type are removed from the set. (This latter rule only has affect when the method group was the result of a member lookup on a type parameter having an effective base class other than object and a non-empty effective interface set.)

- If the resulting set of candidate methods is empty, then further processing along the following steps are abandoned, and instead an attempt is made to process the invocation as an extension method invocation ([Extension method invocations](#)). If this fails, then no applicable methods exist, and a binding-time error occurs.
- The best method of the set of candidate methods is identified using the overload resolution rules of [Overload resolution](#). If a single best method cannot be identified, the method invocation is ambiguous, and a binding-time error occurs. When performing overload resolution, the parameters of a generic method are considered after substituting the type arguments (supplied or inferred) for the corresponding method type parameters.
- Final validation of the chosen best method is performed:
 - The method is validated in the context of the method group: If the best method is a static method, the method group must have resulted from a *simple_name* or a *member_access* through a type. If the best method is an instance method, the method group must have resulted from a *simple_name*, a *member_access* through a variable or value, or a *base_access*. If neither of these requirements is true, a binding-time error occurs.
 - If the best method is a generic method, the type arguments (supplied or inferred) are checked against the constraints ([Satisfying constraints](#)) declared on the generic method. If any type argument does not satisfy the corresponding constraint(s) on the type parameter, a binding-time error occurs.

Once a method has been selected and validated at binding-time by the above steps, the actual run-time invocation is processed according to the rules of function member invocation described in [Compile-time checking of dynamic overload resolution](#).

The intuitive effect of the resolution rules described above is as follows: To locate the particular method invoked by a method invocation, start with the type indicated by the method invocation and proceed up the inheritance chain until at least one applicable, accessible, non-override method declaration is found. Then perform type inference and overload resolution on the set of applicable, accessible, non-override methods declared in that type and invoke the method thus selected. If no method was found, try instead to process the invocation as an extension method invocation.

Extension method invocations

In a method invocation ([Invocations on boxed instances](#)) of one of the forms

```
expr . identifier ( )  
  
expr . identifier ( args )  
  
expr . identifier < typeargs > ( )  
  
expr . identifier < typeargs > ( args )
```

if the normal processing of the invocation finds no applicable methods, an attempt is made to process the construct as an extension method invocation. If *expr* or any of the *args* has compile-time type `dynamic`, extension methods will not apply.

The objective is to find the best *type_name* `c`, so that the corresponding static method invocation can take place:

```
C . identifier ( expr )  
  
C . identifier ( expr , args )  
  
C . identifier < typeargs > ( expr )  
  
C . identifier < typeargs > ( expr , args )
```

An extension method `Ci.Mj` is *eligible* if:

- `Ci` is a non-generic, non-nested class
- The name of `Mj` is *identifier*
- `Mj` is accessible and applicable when applied to the arguments as a static method as shown above
- An implicit identity, reference or boxing conversion exists from *expr* to the type of the first parameter of `Mj`.

The search for `C` proceeds as follows:

- Starting with the closest enclosing namespace declaration, continuing with each enclosing namespace declaration, and ending with the containing compilation unit, successive attempts are made to find a candidate set of extension methods:
 - If the given namespace or compilation unit directly contains non-generic type declarations `Ci` with eligible extension methods `Mj`, then the set of those extension methods is the candidate set.
 - If types `Ci` imported by *using_static_declarations* and directly declared in namespaces imported by *using_namespace_directives* in the given namespace or compilation unit directly contain eligible extension methods `Mj`, then the set of those extension methods is the candidate set.
- If no candidate set is found in any enclosing namespace declaration or compilation unit, a compile-time error occurs.
- Otherwise, overload resolution is applied to the candidate set as described in ([Overload resolution](#)). If no single best method is found, a compile-time error occurs.
- `C` is the type within which the best method is declared as an extension method.

Using `C` as a target, the method call is then processed as a static method invocation ([Compile-time checking of dynamic overload resolution](#)).

The preceding rules mean that instance methods take precedence over extension methods, that extension methods available in inner namespace declarations take precedence over extension methods available in outer namespace declarations, and that extension methods declared directly in a namespace take precedence over extension methods imported into that same namespace with a using namespace directive. For example:

```

public static class E
{
    public static void F(this object obj, int i) { }

    public static void F(this object obj, string s) { }
}

class A { }

class B
{
    public void F(int i) { }
}

class C
{
    public void F(object obj) { }
}

class X
{
    static void Test(A a, B b, C c) {
        a.F(1);           // E.F(object, int)
        a.F("hello");     // E.F(object, string)

        b.F(1);           // B.F(int)
        b.F("hello");     // E.F(object, string)

        c.F(1);           // C.F(object)
        c.F("hello");     // C.F(object)
    }
}

```

In the example, `B`'s method takes precedence over the first extension method, and `C`'s method takes precedence over both extension methods.

```

public static class C
{
    public static void F(this int i) { Console.WriteLine("C.F({0})", i); }
    public static void G(this int i) { Console.WriteLine("C.G({0})", i); }
    public static void H(this int i) { Console.WriteLine("C.H({0})", i); }
}

namespace N1
{
    public static class D
    {
        public static void F(this int i) { Console.WriteLine("D.F({0})", i); }
        public static void G(this int i) { Console.WriteLine("D.G({0})", i); }
    }
}

namespace N2
{
    using N1;

    public static class E
    {
        public static void F(this int i) { Console.WriteLine("E.F({0})", i); }
    }

    class Test
    {
        static void Main(string[] args)
        {
            1.F();
            2.G();
            3.H();
        }
    }
}

```

The output of this example is:

```

E.F(1)
D.G(2)
C.H(3)

```

`D.G` takes precedence over `C.G`, and `E.F` takes precedence over both `D.F` and `C.F`.

Delegate invocations

For a delegate invocation, the *primary_expression* of the *invocation_expression* must be a value of a *delegate_type*. Furthermore, considering the *delegate_type* to be a function member with the same parameter list as the *delegate_type*, the *delegate_type* must be applicable ([Applicable function member](#)) with respect to the *argument_list* of the *invocation_expression*.

The run-time processing of a delegate invocation of the form `D(A)`, where `D` is a *primary_expression* of a *delegate_type* and `A` is an optional *argument_list*, consists of the following steps:

- `D` is evaluated. If this evaluation causes an exception, no further steps are executed.
- The value of `D` is checked to be valid. If the value of `D` is `null`, a `System.NullReferenceException` is thrown and no further steps are executed.
- Otherwise, `D` is a reference to a delegate instance. Function member invocations ([Compile-time checking of dynamic overload resolution](#)) are performed on each of the callable entities in the invocation list of the delegate. For callable entities consisting of an instance and instance method, the instance for the invocation is the instance contained in the callable entity.

Element access

An *element_access* consists of a *primary_no_array_creation_expression*, followed by a "[" token, followed by an *argument_list*, followed by a "]" token. The *argument_list* consists of one or more *arguments*, separated by commas.

```
element_access
    : primary_no_array_creation_expression '[' expression_list ']'
    ;
```

The *argument_list* of an *element_access* is not allowed to contain `ref` or `out` arguments.

An *element_access* is dynamically bound ([Dynamic binding](#)) if at least one of the following holds:

- The *primary_no_array_creation_expression* has compile-time type `dynamic`.
- At least one expression of the *argument_list* has compile-time type `dynamic` and the *primary_no_array_creation_expression* does not have an array type.

In this case the compiler classifies the *element_access* as a value of type `dynamic`. The rules below to determine the meaning of the *element_access* are then applied at run-time, using the run-time type instead of the compile-time type of those of the *primary_no_array_creation_expression* and *argument_list* expressions which have the compile-time type `dynamic`. If the *primary_no_array_creation_expression* does not have compile-time type `dynamic`, then the element access undergoes a limited compile time check as described in [Compile-time checking of dynamic overload resolution](#).

If the *primary_no_array_creation_expression* of an *element_access* is a value of an *array_type*, the *element_access* is an array access ([Array access](#)). Otherwise, the *primary_no_array_creation_expression* must be a variable or value of a class, struct, or interface type that has one or more indexer members, in which case the *element_access* is an indexer access ([Indexer access](#)).

Array access

For an array access, the *primary_no_array_creation_expression* of the *element_access* must be a value of an *array_type*. Furthermore, the *argument_list* of an array access is not allowed to contain named arguments. The number of expressions in the *argument_list* must be the same as the rank of the *array_type*, and each expression must be of type `int`, `uint`, `long`, `ulong`, or must be implicitly convertible to one or more of these types.

The result of evaluating an array access is a variable of the element type of the array, namely the array element selected by the value(s) of the expression(s) in the *argument_list*.

The run-time processing of an array access of the form `P[A]`, where `P` is a *primary_no_array_creation_expression* of an *array_type* and `A` is an *argument_list*, consists of the following steps:

- `P` is evaluated. If this evaluation causes an exception, no further steps are executed.
- The index expressions of the *argument_list* are evaluated in order, from left to right. Following evaluation of each index expression, an implicit conversion ([Implicit conversions](#)) to one of the following types is performed: `int`, `uint`, `long`, `ulong`. The first type in this list for which an implicit conversion exists is chosen. For instance, if the index expression is of type `short` then an implicit conversion to `int` is performed, since implicit conversions from `short` to `int` and from `short` to `long` are possible. If evaluation of an index expression or the subsequent implicit conversion causes an exception, then no further index expressions are evaluated and no further steps are executed.
- The value of `P` is checked to be valid. If the value of `P` is `null`, a `System.NullReferenceException` is thrown and no further steps are executed.
- The value of each expression in the *argument_list* is checked against the actual bounds of each dimension of the array instance referenced by `P`. If one or more values are out of range, a

`System.IndexOutOfRangeException` is thrown and no further steps are executed.

- The location of the array element given by the index expression(s) is computed, and this location becomes the result of the array access.

Indexer access

For an indexer access, the *primary_no_array_creation_expression* of the *element_access* must be a variable or value of a class, struct, or interface type, and this type must implement one or more indexers that are applicable with respect to the *argument_list* of the *element_access*.

The binding-time processing of an indexer access of the form `P[A]`, where `P` is a *primary_no_array_creation_expression* of a class, struct, or interface type `T`, and `A` is an *argument_list*, consists of the following steps:

- The set of indexers provided by `T` is constructed. The set consists of all indexers declared in `T` or a base type of `T` that are not `override` declarations and are accessible in the current context ([Member access](#)).
- The set is reduced to those indexers that are applicable and not hidden by other indexers. The following rules are applied to each indexer `S.I` in the set, where `S` is the type in which the indexer `I` is declared:
 - If `I` is not applicable with respect to `A` ([Applicable function member](#)), then `I` is removed from the set.
 - If `I` is applicable with respect to `A` ([Applicable function member](#)), then all indexers declared in a base type of `S` are removed from the set.
 - If `I` is applicable with respect to `A` ([Applicable function member](#)) and `S` is a class type other than `object`, all indexers declared in an interface are removed from the set.
- If the resulting set of candidate indexers is empty, then no applicable indexers exist, and a binding-time error occurs.
- The best indexer of the set of candidate indexers is identified using the overload resolution rules of [Overload resolution](#). If a single best indexer cannot be identified, the indexer access is ambiguous, and a binding-time error occurs.
- The index expressions of the *argument_list* are evaluated in order, from left to right. The result of processing the indexer access is an expression classified as an indexer access. The indexer access expression references the indexer determined in the step above, and has an associated instance expression of `P` and an associated argument list of `A`.

Depending on the context in which it is used, an indexer access causes invocation of either the *get accessor* or the *set accessor* of the indexer. If the indexer access is the target of an assignment, the *set accessor* is invoked to assign a new value ([Simple assignment](#)). In all other cases, the *get accessor* is invoked to obtain the current value ([Values of expressions](#)).

This access

A *this_access* consists of the reserved word `this`.

```
this_access
: 'this'
;
```

A *this_access* is permitted only in the *block* of an instance constructor, an instance method, or an instance accessor. It has one of the following meanings:

- When `this` is used in a *primary_expression* within an instance constructor of a class, it is classified as a value. The type of the value is the instance type ([The instance type](#)) of the class within which the usage occurs, and the value is a reference to the object being constructed.
- When `this` is used in a *primary_expression* within an instance method or instance accessor of a class, it is classified as a value. The type of the value is the instance type ([The instance type](#)) of the class within which

the usage occurs, and the value is a reference to the object for which the method or accessor was invoked.

- When `this` is used in a *primary_expression* within an instance constructor of a struct, it is classified as a variable. The type of the variable is the instance type ([The instance type](#)) of the struct within which the usage occurs, and the variable represents the struct being constructed. The `this` variable of an instance constructor of a struct behaves exactly the same as an `out` parameter of the struct type—in particular, this means that the variable must be definitely assigned in every execution path of the instance constructor.
- When `this` is used in a *primary_expression* within an instance method or instance accessor of a struct, it is classified as a variable. The type of the variable is the instance type ([The instance type](#)) of the struct within which the usage occurs.
 - If the method or accessor is not an iterator ([Iterators](#)), the `this` variable represents the struct for which the method or accessor was invoked, and behaves exactly the same as a `ref` parameter of the struct type.
 - If the method or accessor is an iterator, the `this` variable represents a copy of the struct for which the method or accessor was invoked, and behaves exactly the same as a value parameter of the struct type.

Use of `this` in a *primary_expression* in a context other than the ones listed above is a compile-time error. In particular, it is not possible to refer to `this` in a static method, a static property accessor, or in a *variable_initializer* of a field declaration.

Base access

A *base_access* consists of the reserved word `base` followed by either a `.` token and an identifier or an *argument_list* enclosed in square brackets:

```
base_access
: 'base' '.' identifier
| 'base' '[' expression_list ']'
;
```

A *base_access* is used to access base class members that are hidden by similarly named members in the current class or struct. A *base_access* is permitted only in the *block* of an instance constructor, an instance method, or an instance accessor. When `base.I` occurs in a class or struct, `I` must denote a member of the base class of that class or struct. Likewise, when `base[E]` occurs in a class, an applicable indexer must exist in the base class.

At binding-time, *base_access* expressions of the form `base.I` and `base[E]` are evaluated exactly as if they were written `((B)this).I` and `((B)this)[E]`, where `B` is the base class of the class or struct in which the construct occurs. Thus, `base.I` and `base[E]` correspond to `this.I` and `this[E]`, except `this` is viewed as an instance of the base class.

When a *base_access* references a virtual function member (a method, property, or indexer), the determination of which function member to invoke at run-time ([Compile-time checking of dynamic overload resolution](#)) is changed. The function member that is invoked is determined by finding the most derived implementation ([Virtual methods](#)) of the function member with respect to `B` (instead of with respect to the run-time type of `this`, as would be usual in a non-base access). Thus, within an `override` of a `virtual` function member, a *base_access* can be used to invoke the inherited implementation of the function member. If the function member referenced by a *base_access* is abstract, a binding-time error occurs.

Postfix increment and decrement operators

```

post_increment_expression
    : primary_expression '++'
    ;

post_decrement_expression
    : primary_expression '--'
    ;

```

The operand of a postfix increment or decrement operation must be an expression classified as a variable, a property access, or an indexer access. The result of the operation is a value of the same type as the operand.

If the *primary_expression* has the compile-time type `dynamic` then the operator is dynamically bound ([Dynamic binding](#)), the *post_increment_expression* or *post_decrement_expression* has the compile-time type `dynamic` and the following rules are applied at run-time using the run-time type of the *primary_expression*.

If the operand of a postfix increment or decrement operation is a property or indexer access, the property or indexer must have both a `get` and a `set` accessor. If this is not the case, a binding-time error occurs.

Unary operator overload resolution ([Unary operator overload resolution](#)) is applied to select a specific operator implementation. Predefined `++` and `--` operators exist for the following types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, and any enum type. The predefined `++` operators return the value produced by adding 1 to the operand, and the predefined `--` operators return the value produced by subtracting 1 from the operand. In a `checked` context, if the result of this addition or subtraction is outside the range of the result type and the result type is an integral type or enum type, a `System.OverflowException` is thrown.

The run-time processing of a postfix increment or decrement operation of the form `x++` or `x--` consists of the following steps:

- If `x` is classified as a variable:
 - `x` is evaluated to produce the variable.
 - The value of `x` is saved.
 - The selected operator is invoked with the saved value of `x` as its argument.
 - The value returned by the operator is stored in the location given by the evaluation of `x`.
 - The saved value of `x` becomes the result of the operation.
- If `x` is classified as a property or indexer access:
 - The instance expression (if `x` is not `static`) and the argument list (if `x` is an indexer access) associated with `x` are evaluated, and the results are used in the subsequent `get` and `set` accessor invocations.
 - The `get` accessor of `x` is invoked and the returned value is saved.
 - The selected operator is invoked with the saved value of `x` as its argument.
 - The `set` accessor of `x` is invoked with the value returned by the operator as its `value` argument.
 - The saved value of `x` becomes the result of the operation.

The `++` and `--` operators also support prefix notation ([Prefix increment and decrement operators](#)). Typically, the result of `x++` or `x--` is the value of `x` before the operation, whereas the result of `++x` or `--x` is the value of `x` after the operation. In either case, `x` itself has the same value after the operation.

An `operator ++` or `operator --` implementation can be invoked using either postfix or prefix notation. It is not possible to have separate operator implementations for the two notations.

The new operator

The `new` operator is used to create new instances of types.

There are three forms of `new` expressions:

- Object creation expressions are used to create new instances of class types and value types.
- Array creation expressions are used to create new instances of array types.
- Delegate creation expressions are used to create new instances of delegate types.

The `new` operator implies creation of an instance of a type, but does not necessarily imply dynamic allocation of memory. In particular, instances of value types require no additional memory beyond the variables in which they reside, and no dynamic allocations occur when `new` is used to create instances of value types.

Object creation expressions

An *object_creation_expression* is used to create a new instance of a *class_type* or a *value_type*.

```
object_creation_expression
: 'new' type '(' argument_list? ')' object_or_collection_initializer?
| 'new' type object_or_collection_initializer
;

object_or_collection_initializer
: object_initializer
| collection_initializer
;
```

The *type* of an *object_creation_expression* must be a *class_type*, a *value_type* or a *type_parameter*. The *type* cannot be an `abstract` *class_type*.

The optional *argument_list* ([Argument lists](#)) is permitted only if the *type* is a *class_type* or a *struct_type*.

An object creation expression can omit the constructor argument list and enclosing parentheses provided it includes an object initializer or collection initializer. Omitting the constructor argument list and enclosing parentheses is equivalent to specifying an empty argument list.

Processing of an object creation expression that includes an object initializer or collection initializer consists of first processing the instance constructor and then processing the member or element initializations specified by the object initializer ([Object initializers](#)) or collection initializer ([Collection initializers](#)).

If any of the arguments in the optional *argument_list* has the compile-time type `dynamic` then the *object_creation_expression* is dynamically bound ([Dynamic binding](#)) and the following rules are applied at run-time using the run-time type of those arguments of the *argument_list* that have the compile time type `dynamic`. However, the object creation undergoes a limited compile time check as described in [Compile-time checking of dynamic overload resolution](#).

The binding-time processing of an *object_creation_expression* of the form `new T(A)`, where `T` is a *class_type* or a *value_type* and `A` is an optional *argument_list*, consists of the following steps:

- If `T` is a *value_type* and `A` is not present:
 - The *object_creation_expression* is a default constructor invocation. The result of the *object_creation_expression* is a value of type `T`, namely the default value for `T` as defined in [The System.ValueType type](#).
- Otherwise, if `T` is a *type_parameter* and `A` is not present:
 - If no value type constraint or constructor constraint ([Type parameter constraints](#)) has been specified for `T`, a binding-time error occurs.
 - The result of the *object_creation_expression* is a value of the run-time type that the type parameter has been bound to, namely the result of invoking the default constructor of that type. The run-time type may be a reference type or a value type.
- Otherwise, if `T` is a *class_type* or a *struct_type*:

- If `T` is an `abstract class_type`, a compile-time error occurs.
- The instance constructor to invoke is determined using the overload resolution rules of [Overload resolution](#). The set of candidate instance constructors consists of all accessible instance constructors declared in `T` which are applicable with respect to `A` ([Applicable function member](#)). If the set of candidate instance constructors is empty, or if a single best instance constructor cannot be identified, a binding-time error occurs.
- The result of the *object_creation_expression* is a value of type `T`, namely the value produced by invoking the instance constructor determined in the step above.
- Otherwise, the *object_creation_expression* is invalid, and a binding-time error occurs.

Even if the *object_creation_expression* is dynamically bound, the compile-time type is still `T`.

The run-time processing of an *object_creation_expression* of the form `new T(A)`, where `T` is *class_type* or a *struct_type* and `A` is an optional *argument_list*, consists of the following steps:

- If `T` is a *class_type*:
 - A new instance of class `T` is allocated. If there is not enough memory available to allocate the new instance, a `System.OutOfMemoryException` is thrown and no further steps are executed.
 - All fields of the new instance are initialized to their default values ([Default values](#)).
 - The instance constructor is invoked according to the rules of function member invocation ([Compile-time checking of dynamic overload resolution](#)). A reference to the newly allocated instance is automatically passed to the instance constructor and the instance can be accessed from within that constructor as `this`.
- If `T` is a *struct_type*:
 - An instance of type `T` is created by allocating a temporary local variable. Since an instance constructor of a *struct_type* is required to definitely assign a value to each field of the instance being created, no initialization of the temporary variable is necessary.
 - The instance constructor is invoked according to the rules of function member invocation ([Compile-time checking of dynamic overload resolution](#)). A reference to the newly allocated instance is automatically passed to the instance constructor and the instance can be accessed from within that constructor as `this`.

Object initializers

An *object initializer* specifies values for zero or more fields, properties or indexed elements of an object.

```

object_initializer
    : '{' member_initializer_list? '}'
    | '{' member_initializer_list ',' '}'
    ;

member_initializer_list
    : member_initializer (',' member_initializer)*
    ;

member_initializer
    : initializer_target '=' initializer_value
    ;

initializer_target
    : identifier
    | '[' argument_list ']'
    ;

initializer_value
    : expression
    | object_or_collection_initializer
    ;

```

An object initializer consists of a sequence of member initializers, enclosed by `{` and `}` tokens and separated by commas. Each *member_initializer* designates a target for the initialization. An *identifier* must name an accessible field or property of the object being initialized, whereas an *argument_list* enclosed in square brackets must specify arguments for an accessible indexer on the object being initialized. It is an error for an object initializer to include more than one member initializer for the same field or property.

Each *initializer_target* is followed by an equals sign and either an expression, an object initializer or a collection initializer. It is not possible for expressions within the object initializer to refer to the newly created object it is initializing.

A member initializer that specifies an expression after the equals sign is processed in the same way as an assignment ([Simple assignment](#)) to the target.

A member initializer that specifies an object initializer after the equals sign is a ***nested object initializer***, i.e. an initialization of an embedded object. Instead of assigning a new value to the field or property, the assignments in the nested object initializer are treated as assignments to members of the field or property. Nested object initializers cannot be applied to properties with a value type, or to read-only fields with a value type.

A member initializer that specifies a collection initializer after the equals sign is an initialization of an embedded collection. Instead of assigning a new collection to the target field, property or indexer, the elements given in the initializer are added to the collection referenced by the target. The target must be of a collection type that satisfies the requirements specified in [Collection initializers](#).

The arguments to an index initializer will always be evaluated exactly once. Thus, even if the arguments end up never getting used (e.g. because of an empty nested initializer), they will be evaluated for their side effects.

The following class represents a point with two coordinates:

```

public class Point
{
    int x, y;

    public int X { get { return x; } set { x = value; } }
    public int Y { get { return y; } set { y = value; } }
}

```

An instance of `Point` can be created and initialized as follows:

```
Point a = new Point { X = 0, Y = 1 };
```

which has the same effect as

```
Point __a = new Point();
__a.X = 0;
__a.Y = 1;
Point a = __a;
```

where `__a` is an otherwise invisible and inaccessible temporary variable. The following class represents a rectangle created from two points:

```
public class Rectangle
{
    Point p1, p2;

    public Point P1 { get { return p1; } set { p1 = value; } }
    public Point P2 { get { return p2; } set { p2 = value; } }
}
```

An instance of `Rectangle` can be created and initialized as follows:

```
Rectangle r = new Rectangle {
    P1 = new Point { X = 0, Y = 1 },
    P2 = new Point { X = 2, Y = 3 }
};
```

which has the same effect as

```
Rectangle __r = new Rectangle();
Point __p1 = new Point();
__p1.X = 0;
__p1.Y = 1;
__r.P1 = __p1;
Point __p2 = new Point();
__p2.X = 2;
__p2.Y = 3;
__r.P2 = __p2;
Rectangle r = __r;
```

where `__r`, `__p1` and `__p2` are temporary variables that are otherwise invisible and inaccessible.

If `Rectangle`'s constructor allocates the two embedded `Point` instances

```
public class Rectangle
{
    Point p1 = new Point();
    Point p2 = new Point();

    public Point P1 { get { return p1; } }
    public Point P2 { get { return p2; } }
}
```

the following construct can be used to initialize the embedded `Point` instances instead of assigning new instances:

```
Rectangle r = new Rectangle {
    P1 = { X = 0, Y = 1 },
    P2 = { X = 2, Y = 3 }
};
```

which has the same effect as

```
Rectangle __r = new Rectangle();
__r.P1.X = 0;
__r.P1.Y = 1;
__r.P2.X = 2;
__r.P2.Y = 3;
Rectangle r = __r;
```

Given an appropriate definition of C, the following example:

```
var c = new C {
    x = true,
    y = { a = "Hello" },
    z = { 1, 2, 3 },
    ["x"] = 5,
    [0,0] = { "a", "b" },
    [1,2] = {}
};
```

is equivalent to this series of assignments:

```
C __c = new C();
__c.x = true;
__c.y.a = "Hello";
__c.z.Add(1);
__c.z.Add(2);
__c.z.Add(3);
string __i1 = "x";
__c[__i1] = 5;
int __i2 = 0, __i3 = 0;
__c[__i2,__i3].Add("a");
__c[__i2,__i3].Add("b");
int __i4 = 1, __i5 = 2;
var c = __c;
```

where `__c`, etc., are generated variables that are invisible and inaccessible to the source code. Note that the arguments for `[0,0]` are evaluated only once, and the arguments for `[1,2]` are evaluated once even though they are never used.

Collection initializers

A collection initializer specifies the elements of a collection.

```

collection_initializer
    : '{' element_initializer_list '}'
    | '{' element_initializer_list ',' '}'
    ;

element_initializer_list
    : element_initializer (',' element_initializer)*
    ;

element_initializer
    : non_assignment_expression
    | '{' expression_list '}'
    ;

expression_list
    : expression (',' expression)*
    ;

```

A collection initializer consists of a sequence of element initializers, enclosed by `{` and `}` tokens and separated by commas. Each element initializer specifies an element to be added to the collection object being initialized, and consists of a list of expressions enclosed by `{` and `}` tokens and separated by commas. A single-expression element initializer can be written without braces, but cannot then be an assignment expression, to avoid ambiguity with member initializers. The *non_assignment_expression* production is defined in [Expression](#).

The following is an example of an object creation expression that includes a collection initializer:

```
List<int> digits = new List<int> { 0, 1, 2, 3, 4, 5, 6, 7, 8, 9 };
```

The collection object to which a collection initializer is applied must be of a type that implements `System.Collections.IEnumerable` or a compile-time error occurs. For each specified element in order, the collection initializer invokes an `Add` method on the target object with the expression list of the element initializer as argument list, applying normal member lookup and overload resolution for each invocation. Thus, the collection object must have an applicable instance or extension method with the name `Add` for each element initializer.

The following class represents a contact with a name and a list of phone numbers:

```

public class Contact
{
    string name;
    List<string> phoneNumbers = new List<string>();

    public string Name { get { return name; } set { name = value; } }

    public List<string> PhoneNumbers { get { return phoneNumbers; } }
}

```

A `List<Contact>` can be created and initialized as follows:

```
var contacts = new List<Contact> {
    new Contact {
        Name = "Chris Smith",
        PhoneNumbers = { "206-555-0101", "425-882-8080" }
    },
    new Contact {
        Name = "Bob Harris",
        PhoneNumbers = { "650-555-0199" }
    }
};
```

which has the same effect as

```
var __clist = new List<Contact>();
Contact __c1 = new Contact();
__c1.Name = "Chris Smith";
__c1.PhoneNumbers.Add("206-555-0101");
__c1.PhoneNumbers.Add("425-882-8080");
__clist.Add(__c1);
Contact __c2 = new Contact();
__c2.Name = "Bob Harris";
__c2.PhoneNumbers.Add("650-555-0199");
__clist.Add(__c2);
var contacts = __clist;
```

where `__clist`, `__c1` and `__c2` are temporary variables that are otherwise invisible and inaccessible.

Array creation expressions

An *array_creation_expression* is used to create a new instance of an *array_type*.

```
array_creation_expression
: 'new' non_array_type '[' expression_list '[' rank_specifier* array_initializer?
| 'new' array_type array_initializer
| 'new' rank_specifier array_initializer
;
```

An array creation expression of the first form allocates an array instance of the type that results from deleting each of the individual expressions from the expression list. For example, the array creation expression `new int[10,20]` produces an array instance of type `int[,]`, and the array creation expression `new int[10][,]` produces an array of type `int[][,]`. Each expression in the expression list must be of type `int`, `uint`, `long`, or `ulong`, or implicitly convertible to one or more of these types. The value of each expression determines the length of the corresponding dimension in the newly allocated array instance. Since the length of an array dimension must be nonnegative, it is a compile-time error to have a *constant_expression* with a negative value in the expression list.

Except in an unsafe context ([Unsafe contexts](#)), the layout of arrays is unspecified.

If an array creation expression of the first form includes an array initializer, each expression in the expression list must be a constant and the rank and dimension lengths specified by the expression list must match those of the array initializer.

In an array creation expression of the second or third form, the rank of the specified array type or rank specifier must match that of the array initializer. The individual dimension lengths are inferred from the number of elements in each of the corresponding nesting levels of the array initializer. Thus, the expression

```
new int[,] {{0, 1}, {2, 3}, {4, 5}}
```

exactly corresponds to

```
new int[3, 2] {{0, 1}, {2, 3}, {4, 5}}
```

An array creation expression of the third form is referred to as an *implicitly typed array creation expression*. It is similar to the second form, except that the element type of the array is not explicitly given, but determined as the best common type ([Finding the best common type of a set of expressions](#)) of the set of expressions in the array initializer. For a multidimensional array, i.e., one where the *rank_specifier* contains at least one comma, this set comprises all *expressions* found in nested *array_initializers*.

Array initializers are described further in [Array initializers](#).

The result of evaluating an array creation expression is classified as a value, namely a reference to the newly allocated array instance. The run-time processing of an array creation expression consists of the following steps:

- The dimension length expressions of the *expression_list* are evaluated in order, from left to right. Following evaluation of each expression, an implicit conversion ([Implicit conversions](#)) to one of the following types is performed: `int`, `uint`, `long`, `ulong`. The first type in this list for which an implicit conversion exists is chosen. If evaluation of an expression or the subsequent implicit conversion causes an exception, then no further expressions are evaluated and no further steps are executed.
- The computed values for the dimension lengths are validated as follows. If one or more of the values are less than zero, a `System.OverflowException` is thrown and no further steps are executed.
- An array instance with the given dimension lengths is allocated. If there is not enough memory available to allocate the new instance, a `System.OutOfMemoryException` is thrown and no further steps are executed.
- All elements of the new array instance are initialized to their default values ([Default values](#)).
- If the array creation expression contains an array initializer, then each expression in the array initializer is evaluated and assigned to its corresponding array element. The evaluations and assignments are performed in the order the expressions are written in the array initializer—in other words, elements are initialized in increasing index order, with the rightmost dimension increasing first. If evaluation of a given expression or the subsequent assignment to the corresponding array element causes an exception, then no further elements are initialized (and the remaining elements will thus have their default values).

An array creation expression permits instantiation of an array with elements of an array type, but the elements of such an array must be manually initialized. For example, the statement

```
int[][] a = new int[100][];
```

creates a single-dimensional array with 100 elements of type `int[]`. The initial value of each element is `null`. It is not possible for the same array creation expression to also instantiate the sub-arrays, and the statement

```
int[][] a = new int[100][5];           // Error
```

results in a compile-time error. Instantiation of the sub-arrays must instead be performed manually, as in

```
int[][] a = new int[100][];  
for (int i = 0; i < 100; i++) a[i] = new int[5];
```

When an array of arrays has a "rectangular" shape, that is when the sub-arrays are all of the same length, it is more efficient to use a multi-dimensional array. In the example above, instantiation of the array of arrays creates 101 objects—one outer array and 100 sub-arrays. In contrast,

```
int[,] = new int[100, 5];
```

creates only a single object, a two-dimensional array, and accomplishes the allocation in a single statement.

The following are examples of implicitly typed array creation expressions:

```
var a = new[] { 1, 10, 100, 1000 };           // int[]
var b = new[] { 1, 1.5, 2, 2.5 };             // double[]
var c = new[,] { { "hello", null }, { "world", "!" } }; // string[,]
var d = new[] { 1, "one", 2, "two" };          // Error
```

The last expression causes a compile-time error because neither `int` nor `string` is implicitly convertible to the other, and so there is no best common type. An explicitly typed array creation expression must be used in this case, for example specifying the type to be `object[]`. Alternatively, one of the elements can be cast to a common base type, which would then become the inferred element type.

Implicitly typed array creation expressions can be combined with anonymous object initializers ([Anonymous object creation expressions](#)) to create anonymously typed data structures. For example:

```
var contacts = new[] {
    new {
        Name = "Chris Smith",
        PhoneNumbers = new[] { "206-555-0101", "425-882-8080" }
    },
    new {
        Name = "Bob Harris",
        PhoneNumbers = new[] { "650-555-0199" }
    }
};
```

Delegate creation expressions

A *delegate_creation_expression* is used to create a new instance of a *delegate_type*.

```
delegate_creation_expression
: 'new' delegate_type '(' expression ')'
```

The argument of a delegate creation expression must be a method group, an anonymous function or a value of either the compile time type `dynamic` or a *delegate_type*. If the argument is a method group, it identifies the method and, for an instance method, the object for which to create a delegate. If the argument is an anonymous function it directly defines the parameters and method body of the delegate target. If the argument is a value it identifies a delegate instance of which to create a copy.

If the *expression* has the compile-time type `dynamic`, the *delegate_creation_expression* is dynamically bound ([Dynamic binding](#)), and the rules below are applied at run-time using the run-time type of the *expression*. Otherwise the rules are applied at compile-time.

The binding-time processing of a *delegate_creation_expression* of the form `new D(E)`, where `D` is a *delegate_type* and `E` is an *expression*, consists of the following steps:

- If `E` is a method group, the delegate creation expression is processed in the same way as a method group conversion ([Method group conversions](#)) from `E` to `D`.
- If `E` is an anonymous function, the delegate creation expression is processed in the same way as an

anonymous function conversion ([Anonymous function conversions](#)) from `E` to `D`.

- If `E` is a value, `E` must be compatible ([Delegate declarations](#)) with `D`, and the result is a reference to a newly created delegate of type `D` that refers to the same invocation list as `E`. If `E` is not compatible with `D`, a compile-time error occurs.

The run-time processing of a *delegate_creation_expression* of the form `new D(E)`, where `D` is a *delegate_type* and `E` is an *expression*, consists of the following steps:

- If `E` is a method group, the delegate creation expression is evaluated as a method group conversion ([Method group conversions](#)) from `E` to `D`.
- If `E` is an anonymous function, the delegate creation is evaluated as an anonymous function conversion from `E` to `D` ([Anonymous function conversions](#)).
- If `E` is a value of a *delegate_type*:
 - `E` is evaluated. If this evaluation causes an exception, no further steps are executed.
 - If the value of `E` is `null`, a `System.NullReferenceException` is thrown and no further steps are executed.
 - A new instance of the delegate type `D` is allocated. If there is not enough memory available to allocate the new instance, a `System.OutOfMemoryException` is thrown and no further steps are executed.
 - The new delegate instance is initialized with the same invocation list as the delegate instance given by `E`.

The invocation list of a delegate is determined when the delegate is instantiated and then remains constant for the entire lifetime of the delegate. In other words, it is not possible to change the target callable entities of a delegate once it has been created. When two delegates are combined or one is removed from another ([Delegate declarations](#)), a new delegate results; no existing delegate has its contents changed.

It is not possible to create a delegate that refers to a property, indexer, user-defined operator, instance constructor, destructor, or static constructor.

As described above, when a delegate is created from a method group, the formal parameter list and return type of the delegate determine which of the overloaded methods to select. In the example

```
delegate double DoubleFunc(double x);

class A
{
    DoubleFunc f = new DoubleFunc(Square);

    static float Square(float x) {
        return x * x;
    }

    static double Square(double x) {
        return x * x;
    }
}
```

the `A.f` field is initialized with a delegate that refers to the second `Square` method because that method exactly matches the formal parameter list and return type of `DoubleFunc`. Had the second `Square` method not been present, a compile-time error would have occurred.

Anonymous object creation expressions

An *anonymous_object_creation_expression* is used to create an object of an anonymous type.

```

anonymous_object_creation_expression
    : 'new' anonymous_object_initializer
    ;

anonymous_object_initializer
    : '{' member_declarator_list? '}'
    | '{' member_declarator_list ',' '}'
    ;

member_declarator_list
    : member_declarator (',' member_declarator)*
    ;

member_declarator
    : simple_name
    | member_access
    | base_access
    | null_conditional_member_access
    | identifier '=' expression
    ;

```

An anonymous object initializer declares an anonymous type and returns an instance of that type. An anonymous type is a nameless class type that inherits directly from `object`. The members of an anonymous type are a sequence of read-only properties inferred from the anonymous object initializer used to create an instance of the type. Specifically, an anonymous object initializer of the form

```
new { p1 = e1, p2 = e2, ..., pn = en }
```

declares an anonymous type of the form

```

class __Anonymous1
{
    private readonly T1 f1;
    private readonly T2 f2;
    ...
    private readonly Tn fn;

    public __Anonymous1(T1 a1, T2 a2, ..., Tn an) {
        f1 = a1;
        f2 = a2;
        ...
        fn = an;
    }

    public T1 p1 { get { return f1; } }
    public T2 p2 { get { return f2; } }
    ...
    public Tn pn { get { return fn; } }

    public override bool Equals(object __o) { ... }
    public override int GetHashCode() { ... }
}

```

where each `Tx` is the type of the corresponding expression `ex`. The expression used in a *member_declarator* must have a type. Thus, it is a compile-time error for an expression in a *member_declarator* to be null or an anonymous function. It is also a compile-time error for the expression to have an unsafe type.

The names of an anonymous type and of the parameter to its `Equals` method are automatically generated by the compiler and cannot be referenced in program text.

Within the same program, two anonymous object initializers that specify a sequence of properties of the same

names and compile-time types in the same order will produce instances of the same anonymous type.

In the example

```
var p1 = new { Name = "Lawnmower", Price = 495.00 };
var p2 = new { Name = "Shovel", Price = 26.95 };
p1 = p2;
```

the assignment on the last line is permitted because `p1` and `p2` are of the same anonymous type.

The `Equals` and `GetHashCode` methods on anonymous types override the methods inherited from `object`, and are defined in terms of the `Equals` and `GetHashCode` of the properties, so that two instances of the same anonymous type are equal if and only if all their properties are equal.

A member declarator can be abbreviated to a simple name ([Type inference](#)), a member access ([Compile-time checking of dynamic overload resolution](#)), a base access ([Base access](#)) or a null-conditional member access ([Null-conditional expressions as projection initializers](#)). This is called a *projection initializer* and is shorthand for a declaration of and assignment to a property with the same name. Specifically, member declarators of the forms

```
identifier
expr.identifier
```

are precisely equivalent to the following, respectively:

```
identifier = identifier
identifier = expr.identifier
```

Thus, in a projection initializer the *identifier* selects both the value and the field or property to which the value is assigned. Intuitively, a projection initializer projects not just a value, but also the name of the value.

The `typeof` operator

The `typeof` operator is used to obtain the `System.Type` object for a type.

```
typeof_expression
: 'typeof' '(' type ')'
| 'typeof' '(' unbound_type_name ')'
| 'typeof' '(' 'void' ')'
;

unbound_type_name
: identifier generic_dimension_specifier?
| identifier '::' identifier generic_dimension_specifier?
| unbound_type_name '.' identifier generic_dimension_specifier?
;

generic_dimension_specifier
: '<' comma* '>'
;

comma
: ','
;
```

The first form of *typeof_expression* consists of a `typeof` keyword followed by a parenthesized *type*. The result of an expression of this form is the `System.Type` object for the indicated type. There is only one `System.Type` object for any given type. This means that for a type `T`, `typeof(T) == typeof(T)` is always true. The *type* cannot

be `dynamic`.

The second form of *typeof_expression* consists of a `typeof` keyword followed by a parenthesized *unbound_type_name*. An *unbound_type_name* is very similar to a *type_name* ([Namespace and type names](#)) except that an *unbound_type_name* contains *generic_dimension_specifiers* where a *type_name* contains *type_argument_lists*. When the operand of a *typeof_expression* is a sequence of tokens that satisfies the grammars of both *unbound_type_name* and *type_name*, namely when it contains neither a *generic_dimension_specifier* nor a *type_argument_list*, the sequence of tokens is considered to be a *type_name*. The meaning of an *unbound_type_name* is determined as follows:

- Convert the sequence of tokens to a *type_name* by replacing each *generic_dimension_specifier* with a *type_argument_list* having the same number of commas and the keyword `object` as each *type_argument*.
- Evaluate the resulting *type_name*, while ignoring all type parameter constraints.
- The *unbound_type_name* resolves to the unbound generic type associated with the resulting constructed type ([Bound and unbound types](#)).

The result of the *typeof_expression* is the `System.Type` object for the resulting unbound generic type.

The third form of *typeof_expression* consists of a `typeof` keyword followed by a parenthesized `void` keyword. The result of an expression of this form is the `System.Type` object that represents the absence of a type. The type object returned by `typeof(void)` is distinct from the type object returned for any type. This special type object is useful in class libraries that allow reflection onto methods in the language, where those methods wish to have a way to represent the return type of any method, including void methods, with an instance of `System.Type`.

The `typeof` operator can be used on a type parameter. The result is the `System.Type` object for the run-time type that was bound to the type parameter. The `typeof` operator can also be used on a constructed type or an unbound generic type ([Bound and unbound types](#)). The `System.Type` object for an unbound generic type is not the same as the `System.Type` object of the instance type. The instance type is always a closed constructed type at run-time so its `System.Type` object depends on the run-time type arguments in use, while the unbound generic type has no type arguments.

The example

```

using System;

class X<T>
{
    public static void PrintTypes() {
        Type[] t = {
            typeof(int),
            typeof(System.Int32),
            typeof(string),
            typeof(double[]),
            typeof(void),
            typeof(T),
            typeof(X<T>),
            typeof(X<X<T>>),
            typeof(X<>)
        };
        for (int i = 0; i < t.Length; i++) {
            Console.WriteLine(t[i]);
        }
    }
}

class Test
{
    static void Main() {
        X<int>.PrintTypes();
    }
}

```

produces the following output:

```

System.Int32
System.Int32
System.String
System.Double[]
System.Void
System.Int32
X`1[System.Int32]
X`1[X`1[System.Int32]]
X`1[T]

```

Note that `int` and `System.Int32` are the same type.

Also note that the result of `typeof(X<>)` does not depend on the type argument but the result of `typeof(X<T>)` does.

The checked and unchecked operators

The `checked` and `unchecked` operators are used to control the *overflow checking context* for integral-type arithmetic operations and conversions.

```

checked_expression
: 'checked' '(' expression ')'
;

unchecked_expression
: 'unchecked' '(' expression ')'
;

```

The `checked` operator evaluates the contained expression in a checked context, and the `unchecked` operator evaluates the contained expression in an unchecked context. A *checked_expression* or *unchecked_expression* corresponds exactly to a *parenthesized_expression* ([Parenthesized expressions](#)), except that the contained

expression is evaluated in the given overflow checking context.

The overflow checking context can also be controlled through the `checked` and `unchecked` statements ([The checked and unchecked statements](#)).

The following operations are affected by the overflow checking context established by the `checked` and `unchecked` operators and statements:

- The predefined `++` and `--` unary operators ([Postfix increment and decrement operators](#) and [Prefix increment and decrement operators](#)), when the operand is of an integral type.
- The predefined `-` unary operator ([Unary minus operator](#)), when the operand is of an integral type.
- The predefined `+`, `-`, `*`, and `/` binary operators ([Arithmetic operators](#)), when both operands are of integral types.
- Explicit numeric conversions ([Explicit numeric conversions](#)) from one integral type to another integral type, or from `float` or `double` to an integral type.

When one of the above operations produce a result that is too large to represent in the destination type, the context in which the operation is performed controls the resulting behavior:

- In a `checked` context, if the operation is a constant expression ([Constant expressions](#)), a compile-time error occurs. Otherwise, when the operation is performed at run-time, a `System.OverflowException` is thrown.
- In an `unchecked` context, the result is truncated by discarding any high-order bits that do not fit in the destination type.

For non-constant expressions (expressions that are evaluated at run-time) that are not enclosed by any `checked` or `unchecked` operators or statements, the default overflow checking context is `unchecked` unless external factors (such as compiler switches and execution environment configuration) call for `checked` evaluation.

For constant expressions (expressions that can be fully evaluated at compile-time), the default overflow checking context is always `checked`. Unless a constant expression is explicitly placed in an `unchecked` context, overflows that occur during the compile-time evaluation of the expression always cause compile-time errors.

The body of an anonymous function is not affected by `checked` or `unchecked` contexts in which the anonymous function occurs.

In the example

```
class Test
{
    static readonly int x = 1000000;
    static readonly int y = 1000000;

    static int F() {
        return checked(x * y);    // Throws OverflowException
    }

    static int G() {
        return unchecked(x * y); // Returns -727379968
    }

    static int H() {
        return x * y;            // Depends on default
    }
}
```

no compile-time errors are reported since neither of the expressions can be evaluated at compile-time. At run-time, the `F` method throws a `System.OverflowException`, and the `G` method returns -727379968 (the lower 32 bits of the out-of-range result). The behavior of the `H` method depends on the default overflow checking

context for the compilation, but it is either the same as `F` or the same as `G`.

In the example

```
class Test
{
    const int x = 1000000;
    const int y = 1000000;

    static int F() {
        return checked(x * y);    // Compile error, overflow
    }

    static int G() {
        return unchecked(x * y); // Returns -727379968
    }

    static int H() {
        return x * y;            // Compile error, overflow
    }
}
```

the overflows that occur when evaluating the constant expressions in `F` and `H` cause compile-time errors to be reported because the expressions are evaluated in a `checked` context. An overflow also occurs when evaluating the constant expression in `G`, but since the evaluation takes place in an `unchecked` context, the overflow is not reported.

The `checked` and `unchecked` operators only affect the overflow checking context for those operations that are textually contained within the "`(`" and "`)`" tokens. The operators have no effect on function members that are invoked as a result of evaluating the contained expression. In the example

```
class Test
{
    static int Multiply(int x, int y) {
        return x * y;
    }

    static int F() {
        return checked(Multiply(1000000, 1000000));
    }
}
```

the use of `checked` in `F` does not affect the evaluation of `x * y` in `Multiply`, so `x * y` is evaluated in the default overflow checking context.

The `unchecked` operator is convenient when writing constants of the signed integral types in hexadecimal notation. For example:

```
class Test
{
    public const int AllBits = unchecked((int)0xFFFFFFFF);

    public const int HighBit = unchecked((int)0x80000000);
}
```

Both of the hexadecimal constants above are of type `uint`. Because the constants are outside the `int` range, without the `unchecked` operator, the casts to `int` would produce compile-time errors.

The `checked` and `unchecked` operators and statements allow programmers to control certain aspects of some

numeric calculations. However, the behavior of some numeric operators depends on their operands' data types. For example, multiplying two decimals always results in an exception on overflow even within an explicitly `unchecked` construct. Similarly, multiplying two floats never results in an exception on overflow even within an explicitly `checked` construct. In addition, other operators are never affected by the mode of checking, whether default or explicit.

Default value expressions

A default value expression is used to obtain the default value ([Default values](#)) of a type. Typically a default value expression is used for type parameters, since it may not be known if the type parameter is a value type or a reference type. (No conversion exists from the `null` literal to a type parameter unless the type parameter is known to be a reference type.)

```
default_value_expression
    : 'default' '(' type ')'
    ;
```

If the *type* in a *default_value_expression* evaluates at run-time to a reference type, the result is `null` converted to that type. If the *type* in a *default_value_expression* evaluates at run-time to a value type, the result is the *value_type*'s default value ([Default constructors](#)).

A *default_value_expression* is a constant expression ([Constant expressions](#)) if the type is a reference type or a type parameter that is known to be a reference type ([Type parameter constraints](#)). In addition, a *default_value_expression* is a constant expression if the type is one of the following value types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, `bool`, or any enumeration type.

Nameof expressions

A *nameof_expression* is used to obtain the name of a program entity as a constant string.

```
nameof_expression
    : 'nameof' '(' named_entity ')'
    ;

named_entity
    : simple_name
    | named_entity_target '.' identifier type_argument_list?
    ;

named_entity_target
    : 'this'
    | 'base'
    | named_entity
    | predefined_type
    | qualified_alias_member
    ;
```

Grammatically speaking, the *named_entity* operand is always an expression. Because `nameof` is not a reserved keyword, a *nameof* expression is always syntactically ambiguous with an invocation of the simple name `nameof`. For compatibility reasons, if a name lookup ([Simple names](#)) of the name `nameof` succeeds, the expression is treated as an *invocation_expression* -- regardless of whether the invocation is legal. Otherwise it is a *nameof_expression*.

The meaning of the *named_entity* of a *nameof_expression* is the meaning of it as an expression; that is, either as a *simple_name*, a *base_access* or a *member_access*. However, where the lookup described in [Simple names](#) and [Member access](#) results in an error because an instance member was found in a static context, a *nameof_expression* produces no such error.

It is a compile-time error for a *named_entity* designating a method group to have a *type_argument_list*. It is a

compile time error for a *named_entity_target* to have the type `dynamic`.

A *nameof_expression* is a constant expression of type `string`, and has no effect at runtime. Specifically, its *named_entity* is not evaluated, and is ignored for the purposes of definite assignment analysis ([General rules for simple expressions](#)). Its value is the last identifier of the *named_entity* before the optional final *type_argument_list*, transformed in the following way:

- The prefix "`@`", if used, is removed.
- Each *unicode_escape_sequence* is transformed into its corresponding Unicode character.
- Any *formatting_characters* are removed.

These are the same transformations applied in [Identifiers](#) when testing equality between identifiers.

TODO: examples

Anonymous method expressions

An *anonymous_method_expression* is one of two ways of defining an anonymous function. These are further described in [Anonymous function expressions](#).

Unary operators

The `?`, `+`, `-`, `!`, `~`, `++`, `--`, `cast`, and `await` operators are called the unary operators.

```
unary_expression
: primary_expression
| null_conditional_expression
| '+' unary_expression
| '-' unary_expression
| '!' unary_expression
| '~' unary_expression
| pre_increment_expression
| pre_decrement_expression
| cast_expression
| await_expression
| unary_expression_unsafe
;
```

If the operand of a *unary_expression* has the compile-time type `dynamic`, it is dynamically bound ([Dynamic binding](#)). In this case the compile-time type of the *unary_expression* is `dynamic`, and the resolution described below will take place at run-time using the run-time type of the operand.

Null-conditional operator

The null-conditional operator applies a list of operations to its operand only if that operand is non-null. Otherwise the result of applying the operator is `null`.

```
null_conditional_expression
: primary_expression null_conditional_operations
;

null_conditional_operations
: null_conditional_operations? '?' '.' identifier type_argument_list?
| null_conditional_operations? '?' '[' argument_list ']'
| null_conditional_operations '.' identifier type_argument_list?
| null_conditional_operations '[' argument_list ']'
| null_conditional_operations '(' argument_list? ')'
;
```

The list of operations can include member access and element access operations (which may themselves be

null-conditional), as well as invocation.

For example, the expression `a.b?[0]?.c()` is a *null_conditional_expression* with a *primary_expression* `a.b` and *null_conditional_operations* `?[0]` (null-conditional element access), `?.c` (null-conditional member access) and `()` (invocation).

For a *null_conditional_expression* `E` with a *primary_expression* `P`, let `E0` be the expression obtained by textually removing the leading `?` from each of the *null_conditional_operations* of `E` that have one. Conceptually, `E0` is the expression that will be evaluated if none of the null checks represented by the `?`s do find a `null`.

Also, let `E1` be the expression obtained by textually removing the leading `?` from just the first of the *null_conditional_operations* in `E`. This may lead to a *primary-expression* (if there was just one `?`) or to another *null_conditional_expression*.

For example, if `E` is the expression `a.b?[0]?.c()`, then `E0` is the expression `a.b[0].c()` and `E1` is the expression `a.b[0]?.c()`.

If `E0` is classified as nothing, then `E` is classified as nothing. Otherwise `E` is classified as a value.

`E0` and `E1` are used to determine the meaning of `E`:

- If `E` occurs as a *statement_expression* the meaning of `E` is the same as the statement

```
if ((object)P != null) E1;
```

except that `P` is evaluated only once.

- Otherwise, if `E0` is classified as nothing a compile-time error occurs.
- Otherwise, let `T0` be the type of `E0`.
 - If `T0` is a type parameter that is not known to be a reference type or a non-nullable value type, a compile-time error occurs.
 - If `T0` is a non-nullable value type, then the type of `E` is `T0?`, and the meaning of `E` is the same as

```
((object)P == null) ? (T0?)null : E1
```

except that `P` is evaluated only once.

- Otherwise the type of `E` is `T0`, and the meaning of `E` is the same as

```
((object)P == null) ? null : E1
```

except that `P` is evaluated only once.

If `E1` is itself a *null_conditional_expression*, then these rules are applied again, nesting the tests for `null` until there are no further `?`'s, and the expression has been reduced all the way down to the *primary-expression* `E0`.

For example, if the expression `a.b?[0]?.c()` occurs as a *statement-expression*, as in the statement:

```
a.b?[0]?.c();
```

its meaning is equivalent to:

```
if (a.b != null) a.b[0]?.c();
```

which again is equivalent to:

```
if (a.b != null) if (a.b[0] != null) a.b[0].c();
```

Except that `a.b` and `a.b[0]` are evaluated only once.

If it occurs in a context where its value is used, as in:

```
var x = a.b?[0]?.c();
```

and assuming that the type of the final invocation is not a non-nullable value type, its meaning is equivalent to:

```
var x = (a.b == null) ? null : (a.b[0] == null) ? null : a.b[0].c();
```

except that `a.b` and `a.b[0]` are evaluated only once.

Null-conditional expressions as projection initializers

A null-conditional expression is only allowed as a *member_declarator* in an *anonymous_object_creation_expression* ([Anonymous object creation expressions](#)) if it ends with an (optionally null-conditional) member access. Grammatically, this requirement can be expressed as:

```
null_conditional_member_access
: primary_expression null_conditional_operations? '?' '.' identifier type_argument_list?
| primary_expression null_conditional_operations '.' identifier type_argument_list?
;
```

This is a special case of the grammar for *null_conditional_expression* above. The production for *member_declarator* in [Anonymous object creation expressions](#) then includes only *null_conditional_member_access*.

Null-conditional expressions as statement expressions

A null-conditional expression is only allowed as a *statement_expression* ([Expression statements](#)) if it ends with an invocation. Grammatically, this requirement can be expressed as:

```
null_conditional_invocation_expression
: primary_expression null_conditional_operations '(' argument_list? ')'
;
```

This is a special case of the grammar for *null_conditional_expression* above. The production for *statement_expression* in [Expression statements](#) then includes only *null_conditional_invocation_expression*.

Unary plus operator

For an operation of the form `+x`, unary operator overload resolution ([Unary operator overload resolution](#)) is applied to select a specific operator implementation. The operand is converted to the parameter type of the selected operator, and the type of the result is the return type of the operator. The predefined unary plus operators are:

```
int operator +(int x);
uint operator +(uint x);
long operator +(long x);
ulong operator +(ulong x);
float operator +(float x);
double operator +(double x);
decimal operator +(decimal x);
```

For each of these operators, the result is simply the value of the operand.

Unary minus operator

For an operation of the form `-x`, unary operator overload resolution ([Unary operator overload resolution](#)) is applied to select a specific operator implementation. The operand is converted to the parameter type of the selected operator, and the type of the result is the return type of the operator. The predefined negation operators are:

- Integer negation:

```
int operator -(int x);
long operator -(long x);
```

The result is computed by subtracting `x` from zero. If the value of `x` is the smallest representable value of the operand type (-2^{31} for `int` or -2^{63} for `long`), then the mathematical negation of `x` is not representable within the operand type. If this occurs within a `checked` context, a `System.OverflowException` is thrown; if it occurs within an `unchecked` context, the result is the value of the operand and the overflow is not reported.

If the operand of the negation operator is of type `uint`, it is converted to type `long`, and the type of the result is `long`. An exception is the rule that permits the `int` value -2^{31} to be written as a decimal integer literal ([Integer literals](#)).

If the operand of the negation operator is of type `ulong`, a compile-time error occurs. An exception is the rule that permits the `long` value -2^{63} to be written as a decimal integer literal ([Integer literals](#)).

- Floating-point negation:

```
float operator -(float x);
double operator -(double x);
```

The result is the value of `x` with its sign inverted. If `x` is NaN, the result is also NaN.

- Decimal negation:

```
decimal operator -(decimal x);
```

The result is computed by subtracting `x` from zero. Decimal negation is equivalent to using the unary minus operator of type `System.Decimal`.

Logical negation operator

For an operation of the form `!x`, unary operator overload resolution ([Unary operator overload resolution](#)) is applied to select a specific operator implementation. The operand is converted to the parameter type of the selected operator, and the type of the result is the return type of the operator. Only one predefined logical negation operator exists:

```
bool operator !(bool x);
```

This operator computes the logical negation of the operand: If the operand is `true`, the result is `false`. If the operand is `false`, the result is `true`.

Bitwise complement operator

For an operation of the form `~x`, unary operator overload resolution ([Unary operator overload resolution](#)) is applied to select a specific operator implementation. The operand is converted to the parameter type of the selected operator, and the type of the result is the return type of the operator. The predefined bitwise complement operators are:

```
int operator ~(int x);
uint operator ~(uint x);
long operator ~(long x);
ulong operator ~(ulong x);
```

For each of these operators, the result of the operation is the bitwise complement of `x`.

Every enumeration type `E` implicitly provides the following bitwise complement operator:

```
E operator ~(E x);
```

The result of evaluating `~x`, where `x` is an expression of an enumeration type `E` with an underlying type `U`, is exactly the same as evaluating `(E)(~(U)x)`, except that the conversion to `E` is always performed as if in an `unchecked` context ([The checked and unchecked operators](#)).

Prefix increment and decrement operators

```
pre_increment_expression
: '++' unary_expression
;

pre_decrement_expression
: '--' unary_expression
;
```

The operand of a prefix increment or decrement operation must be an expression classified as a variable, a property access, or an indexer access. The result of the operation is a value of the same type as the operand.

If the operand of a prefix increment or decrement operation is a property or indexer access, the property or indexer must have both a `get` and a `set` accessor. If this is not the case, a binding-time error occurs.

Unary operator overload resolution ([Unary operator overload resolution](#)) is applied to select a specific operator implementation. Predefined `++` and `--` operators exist for the following types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, and any enum type. The predefined `++` operators return the value produced by adding 1 to the operand, and the predefined `--` operators return the value produced by subtracting 1 from the operand. In a `checked` context, if the result of this addition or subtraction is outside the range of the result type and the result type is an integral type or enum type, a `System.OverflowException` is thrown.

The run-time processing of a prefix increment or decrement operation of the form `++x` or `--x` consists of the following steps:

- If `x` is classified as a variable:

- `x` is evaluated to produce the variable.
- The selected operator is invoked with the value of `x` as its argument.
- The value returned by the operator is stored in the location given by the evaluation of `x`.
- The value returned by the operator becomes the result of the operation.
- If `x` is classified as a property or indexer access:
 - The instance expression (if `x` is not `static`) and the argument list (if `x` is an indexer access) associated with `x` are evaluated, and the results are used in the subsequent `get` and `set` accessor invocations.
 - The `get` accessor of `x` is invoked.
 - The selected operator is invoked with the value returned by the `get` accessor as its argument.
 - The `set` accessor of `x` is invoked with the value returned by the operator as its `value` argument.
 - The value returned by the operator becomes the result of the operation.

The `++` and `--` operators also support postfix notation ([Postfix increment and decrement operators](#)). Typically, the result of `x++` or `x--` is the value of `x` before the operation, whereas the result of `++x` or `--x` is the value of `x` after the operation. In either case, `x` itself has the same value after the operation.

An `operator++` or `operator--` implementation can be invoked using either postfix or prefix notation. It is not possible to have separate operator implementations for the two notations.

Cast expressions

A *cast_expression* is used to explicitly convert an expression to a given type.

```
cast_expression
: '(' type ')' unary_expression
;
```

A *cast_expression* of the form `(T)E`, where `T` is a *type* and `E` is a *unary_expression*, performs an explicit conversion ([Explicit conversions](#)) of the value of `E` to type `T`. If no explicit conversion exists from `E` to `T`, a binding-time error occurs. Otherwise, the result is the value produced by the explicit conversion. The result is always classified as a value, even if `E` denotes a variable.

The grammar for a *cast_expression* leads to certain syntactic ambiguities. For example, the expression `(x)-y` could either be interpreted as a *cast_expression* (a cast of `-y` to type `x`) or as an *additive_expression* combined with a *parenthesized_expression* (which computes the value `x - y`).

To resolve *cast_expression* ambiguities, the following rule exists: A sequence of one or more *tokens* ([White space](#)) enclosed in parentheses is considered the start of a *cast_expression* only if at least one of the following are true:

- The sequence of tokens is correct grammar for a *type*, but not for an *expression*.
- The sequence of tokens is correct grammar for a *type*, and the token immediately following the closing parentheses is the token `~`, the token `!`, the token `(`, an *identifier* ([Unicode character escape sequences](#)), a *literal* ([Literals](#)), or any *keyword* ([Keywords](#)) except `as` and `is`.

The term "correct grammar" above means only that the sequence of tokens must conform to the particular grammatical production. It specifically does not consider the actual meaning of any constituent identifiers. For example, if `x` and `y` are identifiers, then `x.y` is correct grammar for a type, even if `x.y` doesn't actually denote a type.

From the disambiguation rule it follows that, if `x` and `y` are identifiers, `(x)y`, `(x)(y)`, and `(x)(-y)` are *cast_expressions*, but `(x)-y` is not, even if `x` identifies a type. However, if `x` is a keyword that identifies a predefined type (such as `int`), then all four forms are *cast_expressions* (because such a keyword could not

possibly be an expression by itself).

Await expressions

The `await` operator is used to suspend evaluation of the enclosing `async` function until the asynchronous operation represented by the operand has completed.

```
await_expression
: 'await' unary_expression
;
```

An *await_expression* is only allowed in the body of an `async` function ([Async functions](#)). Within the nearest enclosing `async` function, an *await_expression* may not occur in these places:

- Inside a nested (non-`async`) anonymous function
- Inside the block of a *lock_statement*
- In an unsafe context

Note that an *await_expression* cannot occur in most places within a *query_expression*, because those are syntactically transformed to use non-`async` lambda expressions.

Inside of an `async` function, `await` cannot be used as an identifier. There is therefore no syntactic ambiguity between *await-expressions* and various expressions involving identifiers. Outside of `async` functions, `await` acts as a normal identifier.

The operand of an *await_expression* is called the *task*. It represents an asynchronous operation that may or may not be complete at the time the *await_expression* is evaluated. The purpose of the `await` operator is to suspend execution of the enclosing `async` function until the awaited task is complete, and then obtain its outcome.

Awaitable expressions

The task of an *await* expression is required to be *awaitable*. An expression `t` is awaitable if one of the following holds:

- `t` is of compile time type `dynamic`
- `t` has an accessible instance or extension method called `GetAwaiter` with no parameters and no type parameters, and a return type `A` for which all of the following hold:
 - `A` implements the interface `System.Runtime.CompilerServices.INotifyCompletion` (hereafter known as `INotifyCompletion` for brevity)
 - `A` has an accessible, readable instance property `IsCompleted` of type `bool`
 - `A` has an accessible instance method `GetResult` with no parameters and no type parameters

The purpose of the `GetAwaiter` method is to obtain an *awaiter* for the task. The type `A` is called the *awaiter type* for the *await* expression.

The purpose of the `IsCompleted` property is to determine if the task is already complete. If so, there is no need to suspend evaluation.

The purpose of the `INotifyCompletion.OnCompleted` method is to sign up a "continuation" to the task; i.e. a delegate (of type `System.Action`) that will be invoked once the task is complete.

The purpose of the `GetResult` method is to obtain the outcome of the task once it is complete. This outcome may be successful completion, possibly with a result value, or it may be an exception which is thrown by the `GetResult` method.

Classification of await expressions

The expression `await t` is classified the same way as the expression `(t).GetAwaiter().GetResult()`. Thus, if the return type of `GetResult` is `void`, the *await_expression* is classified as nothing. If it has a non-void return type

`T`, the *await_expression* is classified as a value of type `T`.

Runtime evaluation of await expressions

At runtime, the expression `await t` is evaluated as follows:

- An awaiter `a` is obtained by evaluating the expression `(t).GetAwaiter()`.
- A `bool b` is obtained by evaluating the expression `(a).IsCompleted`.
- If `b` is `false` then evaluation depends on whether `a` implements the interface `System.Runtime.CompilerServices.ICriticalNotifyCompletion` (hereafter known as `ICriticalNotifyCompletion` for brevity). This check is done at binding time; i.e. at runtime if `a` has the compile time type `dynamic`, and at compile time otherwise. Let `r` denote the resumption delegate ([Async functions](#)):
 - If `a` does not implement `ICriticalNotifyCompletion`, then the expression `(a as INotifyCompletion).OnCompleted(r)` is evaluated.
 - If `a` does implement `ICriticalNotifyCompletion`, then the expression `(a as ICriticalNotifyCompletion).UnsafeOnCompleted(r)` is evaluated.
 - Evaluation is then suspended, and control is returned to the current caller of the async function.
- Either immediately after (if `b` was `true`), or upon later invocation of the resumption delegate (if `b` was `false`), the expression `(a).GetResult()` is evaluated. If it returns a value, that value is the result of the *await_expression*. Otherwise the result is nothing.

An awaiter's implementation of the interface methods `INotifyCompletion.OnCompleted` and `ICriticalNotifyCompletion.UnsafeOnCompleted` should cause the delegate `r` to be invoked at most once. Otherwise, the behavior of the enclosing async function is undefined.

Arithmetic operators

The `*`, `/`, `%`, `+`, and `-` operators are called the arithmetic operators.

```
multiplicative_expression
: unary_expression
| multiplicative_expression '*' unary_expression
| multiplicative_expression '/' unary_expression
| multiplicative_expression '%' unary_expression
;

additive_expression
: multiplicative_expression
| additive_expression '+' multiplicative_expression
| additive_expression '-' multiplicative_expression
;
```

If an operand of an arithmetic operator has the compile-time type `dynamic`, then the expression is dynamically bound ([Dynamic binding](#)). In this case the compile-time type of the expression is `dynamic`, and the resolution described below will take place at run-time using the run-time type of those operands that have the compile-time type `dynamic`.

Multiplication operator

For an operation of the form `x * y`, binary operator overload resolution ([Binary operator overload resolution](#)) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined multiplication operators are listed below. The operators all compute the product of `x` and `y`.

- Integer multiplication:

```
int operator *(int x, int y);
uint operator *(uint x, uint y);
long operator *(long x, long y);
ulong operator *(ulong x, ulong y);
```

In a `checked` context, if the product is outside the range of the result type, a `System.OverflowException` is thrown. In an `unchecked` context, overflows are not reported and any significant high-order bits outside the range of the result type are discarded.

- Floating-point multiplication:

```
float operator *(float x, float y);
double operator *(double x, double y);
```

The product is computed according to the rules of IEEE 754 arithmetic. The following table lists the results of all possible combinations of nonzero finite values, zeros, infinities, and NaN's. In the table, `x` and `y` are positive finite values. `z` is the result of `x * y`. If the result is too large for the destination type, `z` is infinity. If the result is too small for the destination type, `z` is zero.

	+Y	-Y	+0	-0	+INF	-INF	NAN
+x	+z	-z	+0	-0	+inf	-inf	NaN
-x	-z	+z	-0	+0	-inf	+inf	NaN
+0	+0	-0	+0	-0	NaN	NaN	NaN
-0	-0	+0	-0	+0	NaN	NaN	NaN
+inf	+inf	-inf	NaN	NaN	+inf	-inf	NaN
-inf	-inf	+inf	NaN	NaN	-inf	+inf	NaN
NaN	NaN	NaN	NaN	NaN	NaN	NaN	NaN

- Decimal multiplication:

```
decimal operator *(decimal x, decimal y);
```

If the resulting value is too large to represent in the `decimal` format, a `System.OverflowException` is thrown. If the result value is too small to represent in the `decimal` format, the result is zero. The scale of the result, before any rounding, is the sum of the scales of the two operands.

Decimal multiplication is equivalent to using the multiplication operator of type `System.Decimal`.

Division operator

For an operation of the form `x / y`, binary operator overload resolution ([Binary operator overload resolution](#)) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined division operators are listed below. The operators all compute the quotient of `x` and `y`.

- Integer division:

```
int operator /(int x, int y);
uint operator /(uint x, uint y);
long operator /(long x, long y);
ulong operator /(ulong x, ulong y);
```

If the value of the right operand is zero, a `System.DivideByZeroException` is thrown.

The division rounds the result towards zero. Thus the absolute value of the result is the largest possible integer that is less than or equal to the absolute value of the quotient of the two operands. The result is zero or positive when the two operands have the same sign and zero or negative when the two operands have opposite signs.

If the left operand is the smallest representable `int` or `long` value and the right operand is `-1`, an overflow occurs. In a `checked` context, this causes a `System.ArithmeticException` (or a subclass thereof) to be thrown. In an `unchecked` context, it is implementation-defined as to whether a `System.ArithmeticException` (or a subclass thereof) is thrown or the overflow goes unreported with the resulting value being that of the left operand.

- Floating-point division:

```
float operator /(float x, float y);
double operator /(double x, double y);
```

The quotient is computed according to the rules of IEEE 754 arithmetic. The following table lists the results of all possible combinations of nonzero finite values, zeros, infinities, and NaN's. In the table, `x` and `y` are positive finite values. `z` is the result of `x / y`. If the result is too large for the destination type, `z` is infinity. If the result is too small for the destination type, `z` is zero.

	+Y	-Y	+0	-0	+INF	-INF	NAN
+x	+z	-z	+inf	-inf	+0	-0	NaN
-x	-z	+z	-inf	+inf	-0	+0	NaN
+0	+0	-0	NaN	NaN	+0	-0	NaN
-0	-0	+0	NaN	NaN	-0	+0	NaN
+inf	+inf	-inf	+inf	-inf	NaN	NaN	NaN
-inf	-inf	+inf	-inf	+inf	NaN	NaN	NaN
NaN	NaN	NaN	NaN	NaN	NaN	NaN	NaN

- Decimal division:

```
decimal operator /(decimal x, decimal y);
```

If the value of the right operand is zero, a `System.DivideByZeroException` is thrown. If the resulting value is too large to represent in the `decimal` format, a `System.OverflowException` is thrown. If the result value is too small to represent in the `decimal` format, the result is zero. The scale of the result is the smallest scale that will preserve a result equal to the nearest representable decimal value to the true mathematical result.

Decimal division is equivalent to using the division operator of type `System.Decimal`.

Remainder operator

For an operation of the form `x % y`, binary operator overload resolution ([Binary operator overload resolution](#)) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined remainder operators are listed below. The operators all compute the remainder of the division between `x` and `y`.

- Integer remainder:

```
int operator %(int x, int y);
uint operator %(uint x, uint y);
long operator %(long x, long y);
ulong operator %(ulong x, ulong y);
```

The result of `x % y` is the value produced by `x - (x / y) * y`. If `y` is zero, a `System.DivideByZeroException` is thrown.

If the left operand is the smallest `int` or `long` value and the right operand is `-1`, a `System.OverflowException` is thrown. In no case does `x % y` throw an exception where `x / y` would not throw an exception.

- Floating-point remainder:

```
float operator %(float x, float y);
double operator %(double x, double y);
```

The following table lists the results of all possible combinations of nonzero finite values, zeros, infinities, and NaN's. In the table, `x` and `y` are positive finite values. `z` is the result of `x % y` and is computed as `x - n * y`, where `n` is the largest possible integer that is less than or equal to `x / y`. This method of computing the remainder is analogous to that used for integer operands, but differs from the IEEE 754 definition (in which `n` is the integer closest to `x / y`).

	+Y	-Y	+0	-0	+INF	-INF	NaN
+x	+z	+z	NaN	NaN	x	x	NaN
-x	-z	-z	NaN	NaN	-x	-x	NaN
+0	+0	+0	NaN	NaN	+0	+0	NaN
-0	-0	-0	NaN	NaN	-0	-0	NaN
+inf	NaN	NaN	NaN	NaN	NaN	NaN	NaN
-inf	NaN	NaN	NaN	NaN	NaN	NaN	NaN
NaN	NaN	NaN	NaN	NaN	NaN	NaN	NaN

- Decimal remainder:

```
decimal operator %(decimal x, decimal y);
```

If the value of the right operand is zero, a `System.DivideByZeroException` is thrown. The scale of the result, before any rounding, is the larger of the scales of the two operands, and the sign of the result, if non-zero, is the same as that of `x`.

Decimal remainder is equivalent to using the remainder operator of type `System.Decimal`.

Addition operator

For an operation of the form `x + y`, binary operator overload resolution ([Binary operator overload resolution](#)) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined addition operators are listed below. For numeric and enumeration types, the predefined addition operators compute the sum of the two operands. When one or both operands are of type string, the predefined addition operators concatenate the string representation of the operands.

- Integer addition:

```
int operator +(int x, int y);
uint operator +(uint x, uint y);
long operator +(long x, long y);
ulong operator +(ulong x, ulong y);
```

In a `checked` context, if the sum is outside the range of the result type, a `System.OverflowException` is thrown. In an `unchecked` context, overflows are not reported and any significant high-order bits outside the range of the result type are discarded.

- Floating-point addition:

```
float operator +(float x, float y);
double operator +(double x, double y);
```

The sum is computed according to the rules of IEEE 754 arithmetic. The following table lists the results of all possible combinations of nonzero finite values, zeros, infinities, and NaN's. In the table, `x` and `y` are nonzero finite values, and `z` is the result of `x + y`. If `x` and `y` have the same magnitude but opposite signs, `z` is positive zero. If `x + y` is too large to represent in the destination type, `z` is an infinity with the same sign as `x + y`.

	Y	+0	-0	+INF	-INF	NaN
x	z	x	x	+inf	-inf	NaN
+0	y	+0	+0	+inf	-inf	NaN
-0	y	+0	-0	+inf	-inf	NaN
+inf	+inf	+inf	+inf	+inf	NaN	NaN
-inf	-inf	-inf	-inf	NaN	-inf	NaN
NaN	NaN	NaN	NaN	NaN	NaN	NaN

- Decimal addition:

```
decimal operator +(decimal x, decimal y);
```

If the resulting value is too large to represent in the `decimal` format, a `System.OverflowException` is thrown. The scale of the result, before any rounding, is the larger of the scales of the two operands.

Decimal addition is equivalent to using the addition operator of type `System.Decimal`.

- Enumeration addition. Every enumeration type implicitly provides the following predefined operators, where `E` is the enum type, and `U` is the underlying type of `E`:

```
E operator +(E x, U y);
E operator +(U x, E y);
```

At run-time these operators are evaluated exactly as `(E)((U)x + (U)y)`.

- String concatenation:

```
string operator +(string x, string y);
string operator +(string x, object y);
string operator +(object x, string y);
```

These overloads of the binary `+` operator perform string concatenation. If an operand of string concatenation is `null`, an empty string is substituted. Otherwise, any non-string argument is converted to its string representation by invoking the virtual `ToString` method inherited from type `object`. If `ToString` returns `null`, an empty string is substituted.

```
using System;

class Test
{
    static void Main() {
        string s = null;
        Console.WriteLine("s = >" + s + "<");           // displays s = ><
        int i = 1;
        Console.WriteLine("i = " + i);                 // displays i = 1
        float f = 1.2300E+15F;
        Console.WriteLine("f = " + f);                 // displays f = 1.23E+15
        decimal d = 2.900m;
        Console.WriteLine("d = " + d);                 // displays d = 2.900
    }
}
```

The result of the string concatenation operator is a string that consists of the characters of the left operand followed by the characters of the right operand. The string concatenation operator never returns a `null` value. A `System.OutOfMemoryException` may be thrown if there is not enough memory available to allocate the resulting string.

- Delegate combination. Every delegate type implicitly provides the following predefined operator, where `D` is the delegate type:

```
D operator +(D x, D y);
```

The binary `+` operator performs delegate combination when both operands are of some delegate type

`D`. (If the operands have different delegate types, a binding-time error occurs.) If the first operand is `null`, the result of the operation is the value of the second operand (even if that is also `null`). Otherwise, if the second operand is `null`, then the result of the operation is the value of the first operand. Otherwise, the result of the operation is a new delegate instance that, when invoked, invokes the first operand and then invokes the second operand. For examples of delegate combination, see [Subtraction operator](#) and [Delegate invocation](#). Since `System.Delegate` is not a delegate type, `operator +` is not defined for it.

Subtraction operator

For an operation of the form `x - y`, binary operator overload resolution ([Binary operator overload resolution](#)) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined subtraction operators are listed below. The operators all subtract `y` from `x`.

- Integer subtraction:

```
int operator -(int x, int y);
uint operator -(uint x, uint y);
long operator -(long x, long y);
ulong operator -(ulong x, ulong y);
```

In a `checked` context, if the difference is outside the range of the result type, a `System.OverflowException` is thrown. In an `unchecked` context, overflows are not reported and any significant high-order bits outside the range of the result type are discarded.

- Floating-point subtraction:

```
float operator -(float x, float y);
double operator -(double x, double y);
```

The difference is computed according to the rules of IEEE 754 arithmetic. The following table lists the results of all possible combinations of nonzero finite values, zeros, infinities, and NaNs. In the table, `x` and `y` are nonzero finite values, and `z` is the result of `x - y`. If `x` and `y` are equal, `z` is positive zero. If `x - y` is too large to represent in the destination type, `z` is an infinity with the same sign as `x - y`.

	Y	+0	-0	+INF	-INF	NAN
x	z	x	x	-inf	+inf	NaN
+0	-y	+0	+0	-inf	+inf	NaN
-0	-y	-0	+0	-inf	+inf	NaN
+inf	+inf	+inf	+inf	NaN	+inf	NaN
-inf	-inf	-inf	-inf	-inf	NaN	NaN
NaN	NaN	NaN	NaN	NaN	NaN	NaN

- Decimal subtraction:

```
decimal operator -(decimal x, decimal y);
```

If the resulting value is too large to represent in the `decimal` format, a `System.OverflowException` is thrown. The scale of the result, before any rounding, is the larger of the scales of the two operands.

Decimal subtraction is equivalent to using the subtraction operator of type `System.Decimal`.

- Enumeration subtraction. Every enumeration type implicitly provides the following predefined operator, where `E` is the enum type, and `U` is the underlying type of `E`:

```
U operator -(E x, E y);
```

This operator is evaluated exactly as $(U)((U)x - (U)y)$. In other words, the operator computes the difference between the ordinal values of `x` and `y`, and the type of the result is the underlying type of the enumeration.

```
E operator -(E x, U y);
```

This operator is evaluated exactly as $(E)((U)x - y)$. In other words, the operator subtracts a value from the underlying type of the enumeration, yielding a value of the enumeration.

- Delegate removal. Every delegate type implicitly provides the following predefined operator, where `D` is the delegate type:

```
D operator -(D x, D y);
```

The binary `-` operator performs delegate removal when both operands are of some delegate type `D`. If the operands have different delegate types, a binding-time error occurs. If the first operand is `null`, the result of the operation is `null`. Otherwise, if the second operand is `null`, then the result of the operation is the value of the first operand. Otherwise, both operands represent invocation lists ([Delegate declarations](#)) having one or more entries, and the result is a new invocation list consisting of the first operand's list with the second operand's entries removed from it, provided the second operand's list is a proper contiguous sublist of the first's. (To determine sublist equality, corresponding entries are compared as for the delegate equality operator ([Delegate equality operators](#)).) Otherwise, the result is the value of the left operand. Neither of the operands' lists is changed in the process. If the second operand's list matches multiple sublists of contiguous entries in the first operand's list, the right-most matching sublist of contiguous entries is removed. If removal results in an empty list, the result is `null`. For example:

```

delegate void D(int x);

class C
{
    public static void M1(int i) { /* ... */ }
    public static void M2(int i) { /* ... */ }
}

class Test
{
    static void Main() {
        D cd1 = new D(C.M1);
        D cd2 = new D(C.M2);
        D cd3 = cd1 + cd2 + cd2 + cd1;    // M1 + M2 + M2 + M1
        cd3 -= cd1;                       // => M1 + M2 + M2

        cd3 = cd1 + cd2 + cd2 + cd1;      // M1 + M2 + M2 + M1
        cd3 -= cd1 + cd2;                 // => M2 + M1

        cd3 = cd1 + cd2 + cd2 + cd1;      // M1 + M2 + M2 + M1
        cd3 -= cd2 + cd2;                 // => M1 + M1

        cd3 = cd1 + cd2 + cd2 + cd1;      // M1 + M2 + M2 + M1
        cd3 -= cd2 + cd1;                 // => M1 + M2

        cd3 = cd1 + cd2 + cd2 + cd1;      // M1 + M2 + M2 + M1
        cd3 -= cd1 + cd1;                 // => M1 + M2 + M2 + M1
    }
}

```

Shift operators

The `<<` and `>>` operators are used to perform bit shifting operations.

```

shift_expression
: additive_expression
| shift_expression '<<' additive_expression
| shift_expression right_shift additive_expression
;

```

If an operand of a *shift_expression* has the compile-time type `dynamic`, then the expression is dynamically bound ([Dynamic binding](#)). In this case the compile-time type of the expression is `dynamic`, and the resolution described below will take place at run-time using the run-time type of those operands that have the compile-time type `dynamic`.

For an operation of the form `x << count` or `x >> count`, binary operator overload resolution ([Binary operator overload resolution](#)) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

When declaring an overloaded shift operator, the type of the first operand must always be the class or struct containing the operator declaration, and the type of the second operand must always be `int`.

The predefined shift operators are listed below.

- Shift left:

```
int operator <<(int x, int count);
uint operator <<(uint x, int count);
long operator <<(long x, int count);
ulong operator <<(ulong x, int count);
```

The `<<` operator shifts `x` left by a number of bits computed as described below.

The high-order bits outside the range of the result type of `x` are discarded, the remaining bits are shifted left, and the low-order empty bit positions are set to zero.

- Shift right:

```
int operator >>(int x, int count);
uint operator >>(uint x, int count);
long operator >>(long x, int count);
ulong operator >>(ulong x, int count);
```

The `>>` operator shifts `x` right by a number of bits computed as described below.

When `x` is of type `int` or `long`, the low-order bits of `x` are discarded, the remaining bits are shifted right, and the high-order empty bit positions are set to zero if `x` is non-negative and set to one if `x` is negative.

When `x` is of type `uint` or `ulong`, the low-order bits of `x` are discarded, the remaining bits are shifted right, and the high-order empty bit positions are set to zero.

For the predefined operators, the number of bits to shift is computed as follows:

- When the type of `x` is `int` or `uint`, the shift count is given by the low-order five bits of `count`. In other words, the shift count is computed from `count & 0x1F`.
- When the type of `x` is `long` or `ulong`, the shift count is given by the low-order six bits of `count`. In other words, the shift count is computed from `count & 0x3F`.

If the resulting shift count is zero, the shift operators simply return the value of `x`.

Shift operations never cause overflows and produce the same results in `checked` and `unchecked` contexts.

When the left operand of the `>>` operator is of a signed integral type, the operator performs an arithmetic shift right wherein the value of the most significant bit (the sign bit) of the operand is propagated to the high-order empty bit positions. When the left operand of the `>>` operator is of an unsigned integral type, the operator performs a logical shift right wherein high-order empty bit positions are always set to zero. To perform the opposite operation of that inferred from the operand type, explicit casts can be used. For example, if `x` is a variable of type `int`, the operation `unchecked((int)((uint)x >> y))` performs a logical shift right of `x`.

Relational and type-testing operators

The `==`, `!=`, `<`, `>`, `<=`, `>=`, `is` and `as` operators are called the relational and type-testing operators.

```

relational_expression
: shift_expression
| relational_expression '<' shift_expression
| relational_expression '>' shift_expression
| relational_expression '<=' shift_expression
| relational_expression '>=' shift_expression
| relational_expression 'is' type
| relational_expression 'as' type
;

equality_expression
: relational_expression
| equality_expression '==' relational_expression
| equality_expression '!=' relational_expression
;

```

The `is` operator is described in [The is operator](#) and the `as` operator is described in [The as operator](#).

The `==`, `!=`, `<`, `>`, `<=` and `>=` operators are *comparison operators*.

If an operand of a comparison operator has the compile-time type `dynamic`, then the expression is dynamically bound ([Dynamic binding](#)). In this case the compile-time type of the expression is `dynamic`, and the resolution described below will take place at run-time using the run-time type of those operands that have the compile-time type `dynamic`.

For an operation of the form `x op y`, where `op` is a comparison operator, overload resolution ([Binary operator overload resolution](#)) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined comparison operators are described in the following sections. All predefined comparison operators return a result of type `bool`, as described in the following table.

OPERATION	RESULT
<code>x == y</code>	<code>true</code> if <code>x</code> is equal to <code>y</code> , <code>false</code> otherwise
<code>x != y</code>	<code>true</code> if <code>x</code> is not equal to <code>y</code> , <code>false</code> otherwise
<code>x < y</code>	<code>true</code> if <code>x</code> is less than <code>y</code> , <code>false</code> otherwise
<code>x > y</code>	<code>true</code> if <code>x</code> is greater than <code>y</code> , <code>false</code> otherwise
<code>x <= y</code>	<code>true</code> if <code>x</code> is less than or equal to <code>y</code> , <code>false</code> otherwise
<code>x >= y</code>	<code>true</code> if <code>x</code> is greater than or equal to <code>y</code> , <code>false</code> otherwise

Integer comparison operators

The predefined integer comparison operators are:

```

bool operator ==(int x, int y);
bool operator ==(uint x, uint y);
bool operator ==(long x, long y);
bool operator ==(ulong x, ulong y);

bool operator !=(int x, int y);
bool operator !=(uint x, uint y);
bool operator !=(long x, long y);
bool operator !=(ulong x, ulong y);

bool operator <(int x, int y);
bool operator <(uint x, uint y);
bool operator <(long x, long y);
bool operator <(ulong x, ulong y);

bool operator >(int x, int y);
bool operator >(uint x, uint y);
bool operator >(long x, long y);
bool operator >(ulong x, ulong y);

bool operator <=(int x, int y);
bool operator <=(uint x, uint y);
bool operator <=(long x, long y);
bool operator <=(ulong x, ulong y);

bool operator >=(int x, int y);
bool operator >=(uint x, uint y);
bool operator >=(long x, long y);
bool operator >=(ulong x, ulong y);

```

Each of these operators compares the numeric values of the two integer operands and returns a `bool` value that indicates whether the particular relation is `true` or `false`.

Floating-point comparison operators

The predefined floating-point comparison operators are:

```

bool operator ==(float x, float y);
bool operator ==(double x, double y);

bool operator !=(float x, float y);
bool operator !=(double x, double y);

bool operator <(float x, float y);
bool operator <(double x, double y);

bool operator >(float x, float y);
bool operator >(double x, double y);

bool operator <=(float x, float y);
bool operator <=(double x, double y);

bool operator >=(float x, float y);
bool operator >=(double x, double y);

```

The operators compare the operands according to the rules of the IEEE 754 standard:

- If either operand is NaN, the result is `false` for all operators except `!=`, for which the result is `true`. For any two operands, `x != y` always produces the same result as `!(x == y)`. However, when one or both operands are NaN, the `<`, `>`, `<=`, and `>=` operators do not produce the same results as the logical negation of the opposite operator. For example, if either of `x` and `y` is NaN, then `x < y` is `false`, but `!(x >= y)` is `true`.

- When neither operand is NaN, the operators compare the values of the two floating-point operands with respect to the ordering

```
-inf < -max < ... < -min < -0.0 == +0.0 < +min < ... < +max < +inf
```

where `min` and `max` are the smallest and largest positive finite values that can be represented in the given floating-point format. Notable effects of this ordering are:

- Negative and positive zeros are considered equal.
- A negative infinity is considered less than all other values, but equal to another negative infinity.
- A positive infinity is considered greater than all other values, but equal to another positive infinity.

Decimal comparison operators

The predefined decimal comparison operators are:

```
bool operator ==(decimal x, decimal y);
bool operator !=(decimal x, decimal y);
bool operator <(decimal x, decimal y);
bool operator >(decimal x, decimal y);
bool operator <=(decimal x, decimal y);
bool operator >=(decimal x, decimal y);
```

Each of these operators compares the numeric values of the two decimal operands and returns a `bool` value that indicates whether the particular relation is `true` or `false`. Each decimal comparison is equivalent to using the corresponding relational or equality operator of type `System.Decimal`.

Boolean equality operators

The predefined boolean equality operators are:

```
bool operator ==(bool x, bool y);
bool operator !=(bool x, bool y);
```

The result of `==` is `true` if both `x` and `y` are `true` or if both `x` and `y` are `false`. Otherwise, the result is `false`.

The result of `!=` is `false` if both `x` and `y` are `true` or if both `x` and `y` are `false`. Otherwise, the result is `true`. When the operands are of type `bool`, the `!=` operator produces the same result as the `^` operator.

Enumeration comparison operators

Every enumeration type implicitly provides the following predefined comparison operators:

```
bool operator ==(E x, E y);
bool operator !=(E x, E y);
bool operator <(E x, E y);
bool operator >(E x, E y);
bool operator <=(E x, E y);
bool operator >=(E x, E y);
```

The result of evaluating `x op y`, where `x` and `y` are expressions of an enumeration type `E` with an underlying type `U`, and `op` is one of the comparison operators, is exactly the same as evaluating `((U)x) op ((U)y)`. In other words, the enumeration type comparison operators simply compare the underlying integral values of the two operands.

Reference type equality operators

The predefined reference type equality operators are:

```
bool operator ==(object x, object y);
bool operator !=(object x, object y);
```

The operators return the result of comparing the two references for equality or non-equality.

Since the predefined reference type equality operators accept operands of type `object`, they apply to all types that do not declare applicable `operator ==` and `operator !=` members. Conversely, any applicable user-defined equality operators effectively hide the predefined reference type equality operators.

The predefined reference type equality operators require one of the following:

- Both operands are a value of a type known to be a *reference_type* or the literal `null`. Furthermore, an explicit reference conversion ([Explicit reference conversions](#)) exists from the type of either operand to the type of the other operand.
- One operand is a value of type `T` where `T` is a *type_parameter* and the other operand is the literal `null`. Furthermore `T` does not have the value type constraint.

Unless one of these conditions are true, a binding-time error occurs. Notable implications of these rules are:

- It is a binding-time error to use the predefined reference type equality operators to compare two references that are known to be different at binding-time. For example, if the binding-time types of the operands are two class types `A` and `B`, and if neither `A` nor `B` derives from the other, then it would be impossible for the two operands to reference the same object. Thus, the operation is considered a binding-time error.
- The predefined reference type equality operators do not permit value type operands to be compared. Therefore, unless a struct type declares its own equality operators, it is not possible to compare values of that struct type.
- The predefined reference type equality operators never cause boxing operations to occur for their operands. It would be meaningless to perform such boxing operations, since references to the newly allocated boxed instances would necessarily differ from all other references.
- If an operand of a type parameter type `T` is compared to `null`, and the run-time type of `T` is a value type, the result of the comparison is `false`.

The following example checks whether an argument of an unconstrained type parameter type is `null`.

```
class C<T>
{
    void F(T x) {
        if (x == null) throw new ArgumentNullException();
        ...
    }
}
```

The `x == null` construct is permitted even though `T` could represent a value type, and the result is simply defined to be `false` when `T` is a value type.

For an operation of the form `x == y` or `x != y`, if any applicable `operator ==` or `operator !=` exists, the operator overload resolution ([Binary operator overload resolution](#)) rules will select that operator instead of the predefined reference type equality operator. However, it is always possible to select the predefined reference type equality operator by explicitly casting one or both of the operands to type `object`. The example

```
using System;

class Test
{
    static void Main() {
        string s = "Test";
        string t = string.Copy(s);
        Console.WriteLine(s == t);
        Console.WriteLine((object)s == t);
        Console.WriteLine(s == (object)t);
        Console.WriteLine((object)s == (object)t);
    }
}
```

produces the output

```
True
False
False
False
```

The `s` and `t` variables refer to two distinct `string` instances containing the same characters. The first comparison outputs `True` because the predefined string equality operator ([String equality operators](#)) is selected when both operands are of type `string`. The remaining comparisons all output `False` because the predefined reference type equality operator is selected when one or both of the operands are of type `object`.

Note that the above technique is not meaningful for value types. The example

```
class Test
{
    static void Main() {
        int i = 123;
        int j = 123;
        System.Console.WriteLine((object)i == (object)j);
    }
}
```

outputs `False` because the casts create references to two separate instances of boxed `int` values.

String equality operators

The predefined string equality operators are:

```
bool operator ==(string x, string y);
bool operator !=(string x, string y);
```

Two `string` values are considered equal when one of the following is true:

- Both values are `null`.
- Both values are non-null references to string instances that have identical lengths and identical characters in each character position.

The string equality operators compare string values rather than string references. When two separate string instances contain the exact same sequence of characters, the values of the strings are equal, but the references are different. As described in [Reference type equality operators](#), the reference type equality operators can be used to compare string references instead of string values.

Delegate equality operators

Every delegate type implicitly provides the following predefined comparison operators:

```
bool operator ==(System.Delegate x, System.Delegate y);
bool operator !=(System.Delegate x, System.Delegate y);
```

Two delegate instances are considered equal as follows:

- If either of the delegate instances is `null`, they are equal if and only if both are `null`.
- If the delegates have different run-time type they are never equal.
- If both of the delegate instances have an invocation list ([Delegate declarations](#)), those instances are equal if and only if their invocation lists are the same length, and each entry in one's invocation list is equal (as defined below) to the corresponding entry, in order, in the other's invocation list.

The following rules govern the equality of invocation list entries:

- If two invocation list entries both refer to the same static method then the entries are equal.
- If two invocation list entries both refer to the same non-static method on the same target object (as defined by the reference equality operators) then the entries are equal.
- Invocation list entries produced from evaluation of semantically identical *anonymous_method_expressions* or *lambda_expressions* with the same (possibly empty) set of captured outer variable instances are permitted (but not required) to be equal.

Equality operators and null

The `==` and `!=` operators permit one operand to be a value of a nullable type and the other to be the `null` literal, even if no predefined or user-defined operator (in unlifted or lifted form) exists for the operation.

For an operation of one of the forms

```
x == null
null == x
x != null
null != x
```

where `x` is an expression of a nullable type, if operator overload resolution ([Binary operator overload resolution](#)) fails to find an applicable operator, the result is instead computed from the `HasValue` property of `x`. Specifically, the first two forms are translated into `!x.HasValue`, and last two forms are translated into `x.HasValue`.

The is operator

The `is` operator is used to dynamically check if the run-time type of an object is compatible with a given type. The result of the operation `E is T`, where `E` is an expression and `T` is a type, is a boolean value indicating whether `E` can successfully be converted to type `T` by a reference conversion, a boxing conversion, or an unboxing conversion. The operation is evaluated as follows, after type arguments have been substituted for all type parameters:

- If `E` is an anonymous function, a compile-time error occurs
- If `E` is a method group or the `null` literal, or if the type of `E` is a reference type or a nullable type and the value of `E` is null, the result is false.
- Otherwise, let `D` represent the dynamic type of `E` as follows:
 - If the type of `E` is a reference type, `D` is the run-time type of the instance reference by `E`.
 - If the type of `E` is a nullable type, `D` is the underlying type of that nullable type.
 - If the type of `E` is a non-nullable value type, `D` is the type of `E`.
- The result of the operation depends on `D` and `T` as follows:

- If `T` is a reference type, the result is true if `D` and `T` are the same type, if `D` is a reference type and an implicit reference conversion from `D` to `T` exists, or if `D` is a value type and a boxing conversion from `D` to `T` exists.
- If `T` is a nullable type, the result is true if `D` is the underlying type of `T`.
- If `T` is a non-nullable value type, the result is true if `D` and `T` are the same type.
- Otherwise, the result is false.

Note that user defined conversions, are not considered by the `is` operator.

The `as` operator

The `as` operator is used to explicitly convert a value to a given reference type or nullable type. Unlike a cast expression ([Cast expressions](#)), the `as` operator never throws an exception. Instead, if the indicated conversion is not possible, the resulting value is `null`.

In an operation of the form `E as T`, `E` must be an expression and `T` must be a reference type, a type parameter known to be a reference type, or a nullable type. Furthermore, at least one of the following must be true, or otherwise a compile-time error occurs:

- An identity ([Identity conversion](#)), implicit nullable ([Implicit nullable conversions](#)), implicit reference ([Implicit reference conversions](#)), boxing ([Boxing conversions](#)), explicit nullable ([Explicit nullable conversions](#)), explicit reference ([Explicit reference conversions](#)), or unboxing ([Unboxing conversions](#)) conversion exists from `E` to `T`.
- The type of `E` or `T` is an open type.
- `E` is the `null` literal.

If the compile-time type of `E` is not `dynamic`, the operation `E as T` produces the same result as

```
E is T ? (T)(E) : (T)null
```

except that `E` is only evaluated once. The compiler can be expected to optimize `E as T` to perform at most one dynamic type check as opposed to the two dynamic type checks implied by the expansion above.

If the compile-time type of `E` is `dynamic`, unlike the cast operator the `as` operator is not dynamically bound ([Dynamic binding](#)). Therefore the expansion in this case is:

```
E is T ? (T)(object)(E) : (T)null
```

Note that some conversions, such as user defined conversions, are not possible with the `as` operator and should instead be performed using cast expressions.

In the example

```

class X
{
    public string F(object o) {
        return o as string;          // OK, string is a reference type
    }

    public T G<T>(object o) where T: Attribute {
        return o as T;               // Ok, T has a class constraint
    }

    public U H<U>(object o) {
        return o as U;               // Error, U is unconstrained
    }
}

```

the type parameter `T` of `G` is known to be a reference type, because it has the class constraint. The type parameter `U` of `H` is not however; hence the use of the `as` operator in `H` is disallowed.

Logical operators

The `&`, `^`, and `|` operators are called the logical operators.

```

and_expression
: equality_expression
| and_expression '&' equality_expression
;

exclusive_or_expression
: and_expression
| exclusive_or_expression '^' and_expression
;

inclusive_or_expression
: exclusive_or_expression
| inclusive_or_expression '|' exclusive_or_expression
;

```

If an operand of a logical operator has the compile-time type `dynamic`, then the expression is dynamically bound ([Dynamic binding](#)). In this case the compile-time type of the expression is `dynamic`, and the resolution described below will take place at run-time using the run-time type of those operands that have the compile-time type `dynamic`.

For an operation of the form `x op y`, where `op` is one of the logical operators, overload resolution ([Binary operator overload resolution](#)) is applied to select a specific operator implementation. The operands are converted to the parameter types of the selected operator, and the type of the result is the return type of the operator.

The predefined logical operators are described in the following sections.

Integer logical operators

The predefined integer logical operators are:

```

int operator &(int x, int y);
uint operator &(uint x, uint y);
long operator &(long x, long y);
ulong operator &(ulong x, ulong y);

int operator |(int x, int y);
uint operator |(uint x, uint y);
long operator |(long x, long y);
ulong operator |(ulong x, ulong y);

int operator ^(int x, int y);
uint operator ^(uint x, uint y);
long operator ^(long x, long y);
ulong operator ^(ulong x, ulong y);

```

The `&` operator computes the bitwise logical `AND` of the two operands, the `|` operator computes the bitwise logical `OR` of the two operands, and the `^` operator computes the bitwise logical exclusive `OR` of the two operands. No overflows are possible from these operations.

Enumeration logical operators

Every enumeration type `E` implicitly provides the following predefined logical operators:

```

E operator &(E x, E y);
E operator |(E x, E y);
E operator ^(E x, E y);

```

The result of evaluating `x op y`, where `x` and `y` are expressions of an enumeration type `E` with an underlying type `U`, and `op` is one of the logical operators, is exactly the same as evaluating `(E)((U)x op (U)y)`. In other words, the enumeration type logical operators simply perform the logical operation on the underlying type of the two operands.

Boolean logical operators

The predefined boolean logical operators are:

```

bool operator &(bool x, bool y);
bool operator |(bool x, bool y);
bool operator ^(bool x, bool y);

```

The result of `x & y` is `true` if both `x` and `y` are `true`. Otherwise, the result is `false`.

The result of `x | y` is `true` if either `x` or `y` is `true`. Otherwise, the result is `false`.

The result of `x ^ y` is `true` if `x` is `true` and `y` is `false`, or `x` is `false` and `y` is `true`. Otherwise, the result is `false`. When the operands are of type `bool`, the `^` operator computes the same result as the `!=` operator.

Nullable boolean logical operators

The nullable boolean type `bool?` can represent three values, `true`, `false`, and `null`, and is conceptually similar to the three-valued type used for boolean expressions in SQL. To ensure that the results produced by the `&` and `|` operators for `bool?` operands are consistent with SQL's three-valued logic, the following predefined operators are provided:

```

bool? operator &(bool? x, bool? y);
bool? operator |(bool? x, bool? y);

```

The following table lists the results produced by these operators for all combinations of the values `true`, `false`, and `null`.

x	y	x & y	x y
true	true	true	true
true	false	false	true
true	null	null	true
false	true	false	true
false	false	false	false
false	null	false	null
null	true	null	true
null	false	false	null
null	null	null	null

Conditional logical operators

The `&&` and `||` operators are called the conditional logical operators. They are also called the "short-circuiting" logical operators.

```
conditional_and_expression
: inclusive_or_expression
| conditional_and_expression '&&' inclusive_or_expression
;

conditional_or_expression
: conditional_and_expression
| conditional_or_expression '||' conditional_and_expression
;
```

The `&&` and `||` operators are conditional versions of the `&` and `|` operators:

- The operation `x && y` corresponds to the operation `x & y`, except that `y` is evaluated only if `x` is not `false`.
- The operation `x || y` corresponds to the operation `x | y`, except that `y` is evaluated only if `x` is not `true`.

If an operand of a conditional logical operator has the compile-time type `dynamic`, then the expression is dynamically bound ([Dynamic binding](#)). In this case the compile-time type of the expression is `dynamic`, and the resolution described below will take place at run-time using the run-time type of those operands that have the compile-time type `dynamic`.

An operation of the form `x && y` or `x || y` is processed by applying overload resolution ([Binary operator overload resolution](#)) as if the operation was written `x & y` or `x | y`. Then,

- If overload resolution fails to find a single best operator, or if overload resolution selects one of the

predefined integer logical operators, a binding-time error occurs.

- Otherwise, if the selected operator is one of the predefined boolean logical operators ([Boolean logical operators](#)) or nullable boolean logical operators ([Nullable boolean logical operators](#)), the operation is processed as described in [Boolean conditional logical operators](#).
- Otherwise, the selected operator is a user-defined operator, and the operation is processed as described in [User-defined conditional logical operators](#).

It is not possible to directly overload the conditional logical operators. However, because the conditional logical operators are evaluated in terms of the regular logical operators, overloads of the regular logical operators are, with certain restrictions, also considered overloads of the conditional logical operators. This is described further in [User-defined conditional logical operators](#).

Boolean conditional logical operators

When the operands of `&&` or `||` are of type `bool`, or when the operands are of types that do not define an applicable `operator &` or `operator |`, but do define implicit conversions to `bool`, the operation is processed as follows:

- The operation `x && y` is evaluated as `x ? y : false`. In other words, `x` is first evaluated and converted to type `bool`. Then, if `x` is `true`, `y` is evaluated and converted to type `bool`, and this becomes the result of the operation. Otherwise, the result of the operation is `false`.
- The operation `x || y` is evaluated as `x ? true : y`. In other words, `x` is first evaluated and converted to type `bool`. Then, if `x` is `true`, the result of the operation is `true`. Otherwise, `y` is evaluated and converted to type `bool`, and this becomes the result of the operation.

User-defined conditional logical operators

When the operands of `&&` or `||` are of types that declare an applicable user-defined `operator &` or `operator |`, both of the following must be true, where `T` is the type in which the selected operator is declared:

- The return type and the type of each parameter of the selected operator must be `T`. In other words, the operator must compute the logical `AND` or the logical `OR` of two operands of type `T`, and must return a result of type `T`.
- `T` must contain declarations of `operator true` and `operator false`.

A binding-time error occurs if either of these requirements is not satisfied. Otherwise, the `&&` or `||` operation is evaluated by combining the user-defined `operator true` or `operator false` with the selected user-defined operator:

- The operation `x && y` is evaluated as `T.false(x) ? x : T.&(x, y)`, where `T.false(x)` is an invocation of the `operator false` declared in `T`, and `T.&(x, y)` is an invocation of the selected `operator &`. In other words, `x` is first evaluated and `operator false` is invoked on the result to determine if `x` is definitely false. Then, if `x` is definitely false, the result of the operation is the value previously computed for `x`. Otherwise, `y` is evaluated, and the selected `operator &` is invoked on the value previously computed for `x` and the value computed for `y` to produce the result of the operation.
- The operation `x || y` is evaluated as `T.true(x) ? x : T.|(x, y)`, where `T.true(x)` is an invocation of the `operator true` declared in `T`, and `T.|(x, y)` is an invocation of the selected `operator |`. In other words, `x` is first evaluated and `operator true` is invoked on the result to determine if `x` is definitely true. Then, if `x` is definitely true, the result of the operation is the value previously computed for `x`. Otherwise, `y` is evaluated, and the selected `operator |` is invoked on the value previously computed for `x` and the value computed for `y` to produce the result of the operation.

In either of these operations, the expression given by `x` is only evaluated once, and the expression given by `y` is either not evaluated or evaluated exactly once.

For an example of a type that implements `operator true` and `operator false`, see [Database boolean type](#).

The null coalescing operator

The `??` operator is called the null coalescing operator.

```
null_coalescing_expression
: conditional_or_expression
| conditional_or_expression '??' null_coalescing_expression
;
```

A null coalescing expression of the form `a ?? b` requires `a` to be of a nullable type or reference type. If `a` is non-null, the result of `a ?? b` is `a`; otherwise, the result is `b`. The operation evaluates `b` only if `a` is null.

The null coalescing operator is right-associative, meaning that operations are grouped from right to left. For example, an expression of the form `a ?? b ?? c` is evaluated as `a ?? (b ?? c)`. In general terms, an expression of the form `E1 ?? E2 ?? ... ?? En` returns the first of the operands that is non-null, or null if all operands are null.

The type of the expression `a ?? b` depends on which implicit conversions are available on the operands. In order of preference, the type of `a ?? b` is `A0`, `A`, or `B`, where `A` is the type of `a` (provided that `a` has a type), `B` is the type of `b` (provided that `b` has a type), and `A0` is the underlying type of `A` if `A` is a nullable type, or `A` otherwise. Specifically, `a ?? b` is processed as follows:

- If `A` exists and is not a nullable type or a reference type, a compile-time error occurs.
- If `b` is a dynamic expression, the result type is `dynamic`. At run-time, `a` is first evaluated. If `a` is not null, `a` is converted to dynamic, and this becomes the result. Otherwise, `b` is evaluated, and this becomes the result.
- Otherwise, if `A` exists and is a nullable type and an implicit conversion exists from `b` to `A0`, the result type is `A0`. At run-time, `a` is first evaluated. If `a` is not null, `a` is unwrapped to type `A0`, and this becomes the result. Otherwise, `b` is evaluated and converted to type `A0`, and this becomes the result.
- Otherwise, if `A` exists and an implicit conversion exists from `b` to `A`, the result type is `A`. At run-time, `a` is first evaluated. If `a` is not null, `a` becomes the result. Otherwise, `b` is evaluated and converted to type `A`, and this becomes the result.
- Otherwise, if `b` has a type `B` and an implicit conversion exists from `a` to `B`, the result type is `B`. At run-time, `a` is first evaluated. If `a` is not null, `a` is unwrapped to type `A0` (if `A` exists and is nullable) and converted to type `B`, and this becomes the result. Otherwise, `b` is evaluated and becomes the result.
- Otherwise, `a` and `b` are incompatible, and a compile-time error occurs.

Conditional operator

The `?:` operator is called the conditional operator. It is at times also called the ternary operator.

```
conditional_expression
: null_coalescing_expression
| null_coalescing_expression '?' expression ':' expression
;
```

A conditional expression of the form `b ? x : y` first evaluates the condition `b`. Then, if `b` is `true`, `x` is evaluated and becomes the result of the operation. Otherwise, `y` is evaluated and becomes the result of the operation. A conditional expression never evaluates both `x` and `y`.

The conditional operator is right-associative, meaning that operations are grouped from right to left. For

example, an expression of the form `a ? b : c ? d : e` is evaluated as `a ? b : (c ? d : e)`.

The first operand of the `?:` operator must be an expression that can be implicitly converted to `bool`, or an expression of a type that implements `operator true`. If neither of these requirements is satisfied, a compile-time error occurs.

The second and third operands, `x` and `y`, of the `?:` operator control the type of the conditional expression.

- If `x` has type `x` and `y` has type `y` then
 - If an implicit conversion ([Implicit conversions](#)) exists from `x` to `y`, but not from `y` to `x`, then `y` is the type of the conditional expression.
 - If an implicit conversion ([Implicit conversions](#)) exists from `y` to `x`, but not from `x` to `y`, then `x` is the type of the conditional expression.
 - Otherwise, no expression type can be determined, and a compile-time error occurs.
- If only one of `x` and `y` has a type, and both `x` and `y` are implicitly convertible to that type, then that is the type of the conditional expression.
- Otherwise, no expression type can be determined, and a compile-time error occurs.

The run-time processing of a conditional expression of the form `b ? x : y` consists of the following steps:

- First, `b` is evaluated, and the `bool` value of `b` is determined:
 - If an implicit conversion from the type of `b` to `bool` exists, then this implicit conversion is performed to produce a `bool` value.
 - Otherwise, the `operator true` defined by the type of `b` is invoked to produce a `bool` value.
- If the `bool` value produced by the step above is `true`, then `x` is evaluated and converted to the type of the conditional expression, and this becomes the result of the conditional expression.
- Otherwise, `y` is evaluated and converted to the type of the conditional expression, and this becomes the result of the conditional expression.

Anonymous function expressions

An **anonymous function** is an expression that represents an "in-line" method definition. An anonymous function does not have a value or type in and of itself, but is convertible to a compatible delegate or expression tree type. The evaluation of an anonymous function conversion depends on the target type of the conversion: If it is a delegate type, the conversion evaluates to a delegate value referencing the method which the anonymous function defines. If it is an expression tree type, the conversion evaluates to an expression tree which represents the structure of the method as an object structure.

For historical reasons there are two syntactic flavors of anonymous functions, namely *lambda_expressions* and *anonymous_method_expressions*. For almost all purposes, *lambda_expressions* are more concise and expressive than *anonymous_method_expressions*, which remain in the language for backwards compatibility.

```

lambda_expression
  : anonymous_function_signature '=>' anonymous_function_body
  ;

anonymous_method_expression
  : 'delegate' explicit_anonymous_function_signature? block
  ;

anonymous_function_signature
  : explicit_anonymous_function_signature
  | implicit_anonymous_function_signature
  ;

explicit_anonymous_function_signature
  : '(' explicit_anonymous_function_parameter_list? ')'
  ;

explicit_anonymous_function_parameter_list
  : explicit_anonymous_function_parameter (',' explicit_anonymous_function_parameter)*
  ;

explicit_anonymous_function_parameter
  : anonymous_function_parameter_modifier? type identifier
  ;

anonymous_function_parameter_modifier
  : 'ref'
  | 'out'
  ;

implicit_anonymous_function_signature
  : '(' implicit_anonymous_function_parameter_list? ')'
  | implicit_anonymous_function_parameter
  ;

implicit_anonymous_function_parameter_list
  : implicit_anonymous_function_parameter (',' implicit_anonymous_function_parameter)*
  ;

implicit_anonymous_function_parameter
  : identifier
  ;

anonymous_function_body
  : expression
  | block
  ;

```

The `=>` operator has the same precedence as assignment (`=`) and is right-associative.

An anonymous function with the `async` modifier is an async function and follows the rules described in [Async functions](#).

The parameters of an anonymous function in the form of a *lambda_expression* can be explicitly or implicitly typed. In an explicitly typed parameter list, the type of each parameter is explicitly stated. In an implicitly typed parameter list, the types of the parameters are inferred from the context in which the anonymous function occurs—specifically, when the anonymous function is converted to a compatible delegate type or expression tree type, that type provides the parameter types ([Anonymous function conversions](#)).

In an anonymous function with a single, implicitly typed parameter, the parentheses may be omitted from the parameter list. In other words, an anonymous function of the form

```
( param ) => expr
```

can be abbreviated to

```
param => expr
```

The parameter list of an anonymous function in the form of an *anonymous_method_expression* is optional. If given, the parameters must be explicitly typed. If not, the anonymous function is convertible to a delegate with any parameter list not containing `out` parameters.

A *block* body of an anonymous function is reachable ([End points and reachability](#)) unless the anonymous function occurs inside an unreachable statement.

Some examples of anonymous functions follow below:

```
x => x + 1 // Implicitly typed, expression body
x => { return x + 1; } // Implicitly typed, statement body
(int x) => x + 1 // Explicitly typed, expression body
(int x) => { return x + 1; } // Explicitly typed, statement body
(x, y) => x * y // Multiple parameters
() => Console.WriteLine() // No parameters
async (t1,t2) => await t1 + await t2 // Async
delegate (int x) { return x + 1; } // Anonymous method expression
delegate { return 1 + 1; } // Parameter list omitted
```

The behavior of *lambda_expressions* and *anonymous_method_expressions* is the same except for the following points:

- *anonymous_method_expressions* permit the parameter list to be omitted entirely, yielding convertibility to delegate types of any list of value parameters.
- *lambda_expressions* permit parameter types to be omitted and inferred whereas *anonymous_method_expressions* require parameter types to be explicitly stated.
- The body of a *lambda_expression* can be an expression or a statement block whereas the body of an *anonymous_method_expression* must be a statement block.
- Only *lambda_expressions* have conversions to compatible expression tree types ([Expression tree types](#)).

Anonymous function signatures

The optional *anonymous_function_signature* of an anonymous function defines the names and optionally the types of the formal parameters for the anonymous function. The scope of the parameters of the anonymous function is the *anonymous_function_body*. ([Scopes](#)) Together with the parameter list (if given) the anonymous-method-body constitutes a declaration space ([Declarations](#)). It is thus a compile-time error for the name of a parameter of the anonymous function to match the name of a local variable, local constant or parameter whose scope includes the *anonymous_method_expression* or *lambda_expression*.

If an anonymous function has an *explicit_anonymous_function_signature*, then the set of compatible delegate types and expression tree types is restricted to those that have the same parameter types and modifiers in the same order. In contrast to method group conversions ([Method group conversions](#)), contra-variance of anonymous function parameter types is not supported. If an anonymous function does not have an *anonymous_function_signature*, then the set of compatible delegate types and expression tree types is restricted to those that have no `out` parameters.

Note that an *anonymous_function_signature* cannot include attributes or a parameter array. Nevertheless, an *anonymous_function_signature* may be compatible with a delegate type whose parameter list contains a parameter array.

Note also that conversion to an expression tree type, even if compatible, may still fail at compile-time ([Expression tree types](#)).

Anonymous function bodies

The body (*expression* or *block*) of an anonymous function is subject to the following rules:

- If the anonymous function includes a signature, the parameters specified in the signature are available in the body. If the anonymous function has no signature it can be converted to a delegate type or expression type having parameters ([Anonymous function conversions](#)), but the parameters cannot be accessed in the body.
- Except for `ref` or `out` parameters specified in the signature (if any) of the nearest enclosing anonymous function, it is a compile-time error for the body to access a `ref` or `out` parameter.
- When the type of `this` is a struct type, it is a compile-time error for the body to access `this`. This is true whether the access is explicit (as in `this.x`) or implicit (as in `x` where `x` is an instance member of the struct). This rule simply prohibits such access and does not affect whether member lookup results in a member of the struct.
- The body has access to the outer variables ([Outer variables](#)) of the anonymous function. Access of an outer variable will reference the instance of the variable that is active at the time the *lambda_expression* or *anonymous_method_expression* is evaluated ([Evaluation of anonymous function expressions](#)).
- It is a compile-time error for the body to contain a `goto` statement, `break` statement, or `continue` statement whose target is outside the body or within the body of a contained anonymous function.
- A `return` statement in the body returns control from an invocation of the nearest enclosing anonymous function, not from the enclosing function member. An expression specified in a `return` statement must be implicitly convertible to the return type of the delegate type or expression tree type to which the nearest enclosing *lambda_expression* or *anonymous_method_expression* is converted ([Anonymous function conversions](#)).

It is explicitly unspecified whether there is any way to execute the block of an anonymous function other than through evaluation and invocation of the *lambda_expression* or *anonymous_method_expression*. In particular, the compiler may choose to implement an anonymous function by synthesizing one or more named methods or types. The names of any such synthesized elements must be of a form reserved for compiler use.

Overload resolution and anonymous functions

Anonymous functions in an argument list participate in type inference and overload resolution. Please refer to [Type inference](#) and [Overload resolution](#) for the exact rules.

The following example illustrates the effect of anonymous functions on overload resolution.

```
class ItemList<T>: List<T>
{
    public int Sum(Func<T,int> selector) {
        int sum = 0;
        foreach (T item in this) sum += selector(item);
        return sum;
    }

    public double Sum(Func<T,double> selector) {
        double sum = 0;
        foreach (T item in this) sum += selector(item);
        return sum;
    }
}
```

The `ItemList<T>` class has two `Sum` methods. Each takes a `selector` argument, which extracts the value to sum over from a list item. The extracted value can be either an `int` or a `double` and the resulting sum is likewise either an `int` or a `double`.

The `sum` methods could for example be used to compute sums from a list of detail lines in an order.

```
class Detail
{
    public int UnitCount;
    public double UnitPrice;
    ...
}

void ComputeSums() {
    ItemList<Detail> orderDetails = GetOrderDetails(...);
    int totalUnits = orderDetails.Sum(d => d.UnitCount);
    double orderTotal = orderDetails.Sum(d => d.UnitPrice * d.UnitCount);
    ...
}
```

In the first invocation of `orderDetails.Sum`, both `Sum` methods are applicable because the anonymous function `d => d. UnitCount` is compatible with both `Func<Detail,int>` and `Func<Detail,double>`. However, overload resolution picks the first `Sum` method because the conversion to `Func<Detail,int>` is better than the conversion to `Func<Detail,double>`.

In the second invocation of `orderDetails.Sum`, only the second `Sum` method is applicable because the anonymous function `d => d.UnitPrice * d.UnitCount` produces a value of type `double`. Thus, overload resolution picks the second `Sum` method for that invocation.

Anonymous functions and dynamic binding

An anonymous function cannot be a receiver, argument or operand of a dynamically bound operation.

Outer variables

Any local variable, value parameter, or parameter array whose scope includes the *lambda_expression* or *anonymous_method_expression* is called an **outer variable** of the anonymous function. In an instance function member of a class, the `this` value is considered a value parameter and is an outer variable of any anonymous function contained within the function member.

Captured outer variables

When an outer variable is referenced by an anonymous function, the outer variable is said to have been **captured** by the anonymous function. Ordinarily, the lifetime of a local variable is limited to execution of the block or statement with which it is associated ([Local variables](#)). However, the lifetime of a captured outer variable is extended at least until the delegate or expression tree created from the anonymous function becomes eligible for garbage collection.

In the example

```

using System;

delegate int D();

class Test
{
    static D F() {
        int x = 0;
        D result = () => ++x;
        return result;
    }

    static void Main() {
        D d = F();
        Console.WriteLine(d());
        Console.WriteLine(d());
        Console.WriteLine(d());
    }
}

```

the local variable `x` is captured by the anonymous function, and the lifetime of `x` is extended at least until the delegate returned from `F` becomes eligible for garbage collection (which doesn't happen until the very end of the program). Since each invocation of the anonymous function operates on the same instance of `x`, the output of the example is:

```

1
2
3

```

When a local variable or a value parameter is captured by an anonymous function, the local variable or parameter is no longer considered to be a fixed variable ([Fixed and moveable variables](#)), but is instead considered to be a moveable variable. Thus any `unsafe` code that takes the address of a captured outer variable must first use the `fixed` statement to fix the variable.

Note that unlike an uncaptured variable, a captured local variable can be simultaneously exposed to multiple threads of execution.

Instantiation of local variables

A local variable is considered to be *instantiated* when execution enters the scope of the variable. For example, when the following method is invoked, the local variable `x` is instantiated and initialized three times—once for each iteration of the loop.

```

static void F() {
    for (int i = 0; i < 3; i++) {
        int x = i * 2 + 1;
        ...
    }
}

```

However, moving the declaration of `x` outside the loop results in a single instantiation of `x`:

```
static void F() {
    int x;
    for (int i = 0; i < 3; i++) {
        x = i * 2 + 1;
        ...
    }
}
```

When not captured, there is no way to observe exactly how often a local variable is instantiated—because the lifetimes of the instantiations are disjoint, it is possible for each instantiation to simply use the same storage location. However, when an anonymous function captures a local variable, the effects of instantiation become apparent.

The example

```
using System;

delegate void D();

class Test
{
    static D[] F() {
        D[] result = new D[3];
        for (int i = 0; i < 3; i++) {
            int x = i * 2 + 1;
            result[i] = () => { Console.WriteLine(x); };
        }
        return result;
    }

    static void Main() {
        foreach (D d in F()) d();
    }
}
```

produces the output:

```
1
3
5
```

However, when the declaration of `x` is moved outside the loop:

```
static D[] F() {
    D[] result = new D[3];
    int x;
    for (int i = 0; i < 3; i++) {
        x = i * 2 + 1;
        result[i] = () => { Console.WriteLine(x); };
    }
    return result;
}
```

the output is:

```
5
5
5
```

If a for-loop declares an iteration variable, that variable itself is considered to be declared outside of the loop. Thus, if the example is changed to capture the iteration variable itself:

```
static D[] F() {
    D[] result = new D[3];
    for (int i = 0; i < 3; i++) {
        result[i] = () => { Console.WriteLine(i); };
    }
    return result;
}
```

only one instance of the iteration variable is captured, which produces the output:

```
3
3
3
```

It is possible for anonymous function delegates to share some captured variables yet have separate instances of others. For example, if `F` is changed to

```
static D[] F() {
    D[] result = new D[3];
    int x = 0;
    for (int i = 0; i < 3; i++) {
        int y = 0;
        result[i] = () => { Console.WriteLine("{0} {1}", ++x, ++y); };
    }
    return result;
}
```

the three delegates capture the same instance of `x` but separate instances of `y`, and the output is:

```
1 1
2 1
3 1
```

Separate anonymous functions can capture the same instance of an outer variable. In the example:

```
using System;

delegate void Setter(int value);

delegate int Getter();

class Test
{
    static void Main() {
        int x = 0;
        Setter s = (int value) => { x = value; };
        Getter g = () => { return x; };
        s(5);
        Console.WriteLine(g());
        s(10);
        Console.WriteLine(g());
    }
}
```

the two anonymous functions capture the same instance of the local variable `x`, and they can thus

"communicate" through that variable. The output of the example is:

```
5
10
```

Evaluation of anonymous function expressions

An anonymous function `F` must always be converted to a delegate type `D` or an expression tree type `E`, either directly or through the execution of a delegate creation expression `new D(F)`. This conversion determines the result of the anonymous function, as described in [Anonymous function conversions](#).

Query expressions

Query expressions provide a language integrated syntax for queries that is similar to relational and hierarchical query languages such as SQL and XQuery.

```
query_expression
    : from_clause query_body
    ;

from_clause
    : 'from' type? identifier 'in' expression
    ;

query_body
    : query_body_clauses? select_or_group_clause query_continuation?
    ;

query_body_clauses
    : query_body_clause
    | query_body_clauses query_body_clause
    ;

query_body_clause
    : from_clause
    | let_clause
    | where_clause
    | join_clause
    | join_into_clause
    | orderby_clause
    ;

let_clause
    : 'let' identifier '=' expression
    ;

where_clause
    : 'where' boolean_expression
    ;

join_clause
    : 'join' type? identifier 'in' expression 'on' expression 'equals' expression
    ;

join_into_clause
    : 'join' type? identifier 'in' expression 'on' expression 'equals' expression 'into' identifier
    ;

orderby_clause
    : 'orderby' orderings
    ;

orderings
    : ordering (',' ordering)*
```

```

;

ordering
: expression ordering_direction?
;

ordering_direction
: 'ascending'
| 'descending'
;

select_or_group_clause
: select_clause
| group_clause
;

select_clause
: 'select' expression
;

group_clause
: 'group' expression 'by' expression
;

query_continuation
: 'into' identifier query_body
;

```

A query expression begins with a `from` clause and ends with either a `select` or `group` clause. The initial `from` clause can be followed by zero or more `from`, `let`, `where`, `join` or `orderby` clauses. Each `from` clause is a generator introducing a **range variable** which ranges over the elements of a **sequence**. Each `let` clause introduces a range variable representing a value computed by means of previous range variables. Each `where` clause is a filter that excludes items from the result. Each `join` clause compares specified keys of the source sequence with keys of another sequence, yielding matching pairs. Each `orderby` clause reorders items according to specified criteria. The final `select` or `group` clause specifies the shape of the result in terms of the range variables. Finally, an `into` clause can be used to "splice" queries by treating the results of one query as a generator in a subsequent query.

Ambiguities in query expressions

Query expressions contain a number of "contextual keywords", i.e., identifiers that have special meaning in a given context. Specifically these are `from`, `where`, `join`, `on`, `equals`, `into`, `let`, `orderby`, `ascending`, `descending`, `select`, `group` and `by`. In order to avoid ambiguities in query expressions caused by mixed use of these identifiers as keywords or simple names, these identifiers are considered keywords when occurring anywhere within a query expression.

For this purpose, a query expression is any expression that starts with "`from identifier`" followed by any token except "`;`", "`=`" or "`,`".

In order to use these words as identifiers within a query expression, they can be prefixed with "`@`" (**Identifiers**).

Query expression translation

The C# language does not specify the execution semantics of query expressions. Rather, query expressions are translated into invocations of methods that adhere to the *query expression pattern* ([The query expression pattern](#)). Specifically, query expressions are translated into invocations of methods named `Where`, `Select`, `SelectMany`, `Join`, `GroupJoin`, `OrderBy`, `OrderByDescending`, `ThenBy`, `ThenByDescending`, `GroupBy`, and `Cast`. These methods are expected to have particular signatures and result types, as described in [The query expression pattern](#). These methods can be instance methods of the object being queried or extension methods that are external to the object, and they implement the actual execution of the query.

The translation from query expressions to method invocations is a syntactic mapping that occurs before any

type binding or overload resolution has been performed. The translation is guaranteed to be syntactically correct, but it is not guaranteed to produce semantically correct C# code. Following translation of query expressions, the resulting method invocations are processed as regular method invocations, and this may in turn uncover errors, for example if the methods do not exist, if arguments have wrong types, or if the methods are generic and type inference fails.

A query expression is processed by repeatedly applying the following translations until no further reductions are possible. The translations are listed in order of application: each section assumes that the translations in the preceding sections have been performed exhaustively, and once exhausted, a section will not later be revisited in the processing of the same query expression.

Assignment to range variables is not allowed in query expressions. However a C# implementation is permitted to not always enforce this restriction, since this may sometimes not be possible with the syntactic translation scheme presented here.

Certain translations inject range variables with transparent identifiers denoted by `*`. The special properties of transparent identifiers are discussed further in [Transparent identifiers](#).

Select and groupby clauses with continuations

A query expression with a continuation

```
from ... into x ...
```

is translated into

```
from x in ( from ... ) ...
```

The translations in the following sections assume that queries have no `into` continuations.

The example

```
from c in customers
group c by c.Country into g
select new { Country = g.Key, CustCount = g.Count() }
```

is translated into

```
from g in
    from c in customers
    group c by c.Country
select new { Country = g.Key, CustCount = g.Count() }
```

the final translation of which is

```
customers.
  GroupBy(c => c.Country).
  Select(g => new { Country = g.Key, CustCount = g.Count() })
```

Explicit range variable types

A `from` clause that explicitly specifies a range variable type

```
from T x in e
```

is translated into

```
from x in ( e ) . Cast < T > ( )
```

A `join` clause that explicitly specifies a range variable type

```
join T x in e on k1 equals k2
```

is translated into

```
join x in ( e ) . Cast < T > ( ) on k1 equals k2
```

The translations in the following sections assume that queries have no explicit range variable types.

The example

```
from Customer c in customers
where c.City == "London"
select c
```

is translated into

```
from c in customers.Cast<Customer>()
where c.City == "London"
select c
```

the final translation of which is

```
customers.
Cast<Customer>().
Where(c => c.City == "London")
```

Explicit range variable types are useful for querying collections that implement the non-generic `IEnumerable` interface, but not the generic `IEnumerable<T>` interface. In the example above, this would be the case if `customers` were of type `ArrayList`.

Degenerate query expressions

A query expression of the form

```
from x in e select x
```

is translated into

```
( e ) . Select ( x => x )
```

The example

```
from c in customers
select c
```

is translated into

```
customers.Select(c => c)
```

A degenerate query expression is one that trivially selects the elements of the source. A later phase of the translation removes degenerate queries introduced by other translation steps by replacing them with their source. It is important however to ensure that the result of a query expression is never the source object itself, as that would reveal the type and identity of the source to the client of the query. Therefore this step protects degenerate queries written directly in source code by explicitly calling `Select` on the source. It is then up to the implementers of `Select` and other query operators to ensure that these methods never return the source object itself.

From, let, where, join and orderby clauses

A query expression with a second `from` clause followed by a `select` clause

```
from x1 in e1
from x2 in e2
select v
```

is translated into

```
( e1 ). SelectMany( x1 => e2 , ( x1 , x2 ) => v )
```

A query expression with a second `from` clause followed by something other than a `select` clause:

```
from x1 in e1
from x2 in e2
...
```

is translated into

```
from * in ( e1 ). SelectMany( x1 => e2 , ( x1 , x2 ) => new { x1 , x2 } )
...
```

A query expression with a `let` clause

```
from x in e
let y = f
...
```

is translated into

```
from * in ( e ) . Select ( x => new { x , y = f } )
...
```

A query expression with a `where` clause

```
from x in e
where f
...
```

is translated into

```
from x in ( e ) . Where ( x => f )
...
```

A query expression with a `join` clause without an `into` followed by a `select` clause

```
from x1 in e1
join x2 in e2 on k1 equals k2
select v
```

is translated into

```
( e1 ) . Join( e2 , x1 => k1 , x2 => k2 , ( x1 , x2 ) => v )
```

A query expression with a `join` clause without an `into` followed by something other than a `select` clause

```
from x1 in e1
join x2 in e2 on k1 equals k2
...
```

is translated into

```
from * in ( e1 ) . Join( e2 , x1 => k1 , x2 => k2 , ( x1 , x2 ) => new { x1 , x2 })
...
```

A query expression with a `join` clause with an `into` followed by a `select` clause

```
from x1 in e1
join x2 in e2 on k1 equals k2 into g
select v
```

is translated into

```
( e1 ) . GroupJoin( e2 , x1 => k1 , x2 => k2 , ( x1 , g ) => v )
```

A query expression with a `join` clause with an `into` followed by something other than a `select` clause

```
from x1 in e1
join x2 in e2 on k1 equals k2 into g
...
```

is translated into

```
from * in ( e1 ) . GroupJoin( e2 , x1 => k1 , x2 => k2 , ( x1 , g ) => new { x1 , g })
...
```

A query expression with an `orderby` clause

```
from x in e
orderby k1 , k2 , ..., kn
...
```

is translated into

```
from x in ( e ) .  
OrderBy ( x => k1 ) .  
ThenBy ( x => k2 ) .  
... .  
ThenBy ( x => kn )  
...
```

If an ordering clause specifies a `descending` direction indicator, an invocation of `OrderByDescending` or `ThenByDescending` is produced instead.

The following translations assume that there are no `let`, `where`, `join` or `orderby` clauses, and no more than the one initial `from` clause in each query expression.

The example

```
from c in customers  
from o in c.Orders  
select new { c.Name, o.OrderID, o.Total }
```

is translated into

```
customers.  
SelectMany(c => c.Orders,  
    (c,o) => new { c.Name, o.OrderID, o.Total }  
)
```

The example

```
from c in customers  
from o in c.Orders  
orderby o.Total descending  
select new { c.Name, o.OrderID, o.Total }
```

is translated into

```
from * in customers.  
    SelectMany(c => c.Orders, (c,o) => new { c, o })  
orderby o.Total descending  
select new { c.Name, o.OrderID, o.Total }
```

the final translation of which is

```
customers.  
SelectMany(c => c.Orders, (c,o) => new { c, o }).  
OrderByDescending(x => x.o.Total).  
Select(x => new { x.c.Name, x.o.OrderID, x.o.Total })
```

where `x` is a compiler generated identifier that is otherwise invisible and inaccessible.

The example

```

from o in orders
let t = o.Details.Sum(d => d.UnitPrice * d.Quantity)
where t >= 1000
select new { o.OrderID, Total = t }

```

is translated into

```

from * in orders.
    Select(o => new { o, t = o.Details.Sum(d => d.UnitPrice * d.Quantity) })
where t >= 1000
select new { o.OrderID, Total = t }

```

the final translation of which is

```

orders.
Select(o => new { o, t = o.Details.Sum(d => d.UnitPrice * d.Quantity) }).
Where(x => x.t >= 1000).
Select(x => new { x.o.OrderID, Total = x.t })

```

where `x` is a compiler generated identifier that is otherwise invisible and inaccessible.

The example

```

from c in customers
join o in orders on c.CustomerID equals o.CustomerID
select new { c.Name, o.OrderDate, o.Total }

```

is translated into

```

customers.Join(orders, c => c.CustomerID, o => o.CustomerID,
    (c, o) => new { c.Name, o.OrderDate, o.Total })

```

The example

```

from c in customers
join o in orders on c.CustomerID equals o.CustomerID into co
let n = co.Count()
where n >= 10
select new { c.Name, OrderCount = n }

```

is translated into

```

from * in customers.
    GroupJoin(orders, c => c.CustomerID, o => o.CustomerID,
        (c, co) => new { c, co })
let n = co.Count()
where n >= 10
select new { c.Name, OrderCount = n }

```

the final translation of which is

```
customers.
GroupJoin(orders, c => c.CustomerID, o => o.CustomerID,
    (c, co) => new { c, co }).
Select(x => new { x, n = x.co.Count() }).
Where(y => y.n >= 10).
Select(y => new { y.x.c.Name, OrderCount = y.n })
```

where `x` and `y` are compiler generated identifiers that are otherwise invisible and inaccessible.

The example

```
from o in orders
orderby o.Customer.Name, o.Total descending
select o
```

has the final translation

```
orders.
OrderBy(o => o.Customer.Name).
ThenByDescending(o => o.Total)
```

Select clauses

A query expression of the form

```
from x in e select v
```

is translated into

```
( e ) . Select ( x => v )
```

except when `v` is the identifier `x`, the translation is simply

```
( e )
```

For example

```
from c in customers.Where(c => c.City == "London")
select c
```

is simply translated into

```
customers.Where(c => c.City == "London")
```

Groupby clauses

A query expression of the form

```
from x in e group v by k
```

is translated into

```
( e ) . GroupBy ( x => k , x => v )
```

except when v is the identifier x , the translation is

```
( e ) . GroupBy ( x => k )
```

The example

```
from c in customers
group c.Name by c.Country
```

is translated into

```
customers.
  GroupBy(c => c.Country, c => c.Name)
```

Transparent identifiers

Certain translations inject range variables with *transparent identifiers* denoted by `*`. Transparent identifiers are not a proper language feature; they exist only as an intermediate step in the query expression translation process.

When a query translation injects a transparent identifier, further translation steps propagate the transparent identifier into anonymous functions and anonymous object initializers. In those contexts, transparent identifiers have the following behavior:

- When a transparent identifier occurs as a parameter in an anonymous function, the members of the associated anonymous type are automatically in scope in the body of the anonymous function.
- When a member with a transparent identifier is in scope, the members of that member are in scope as well.
- When a transparent identifier occurs as a member declarator in an anonymous object initializer, it introduces a member with a transparent identifier.
- In the translation steps described above, transparent identifiers are always introduced together with anonymous types, with the intent of capturing multiple range variables as members of a single object. An implementation of C# is permitted to use a different mechanism than anonymous types to group together multiple range variables. The following translation examples assume that anonymous types are used, and show how transparent identifiers can be translated away.

The example

```
from c in customers
from o in c.Orders
orderby o.Total descending
select new { c.Name, o.Total }
```

is translated into

```
from * in customers.
  SelectMany(c => c.Orders, (c,o) => new { c, o })
orderby o.Total descending
select new { c.Name, o.Total }
```

which is further translated into

```
customers.
SelectMany(c => c.Orders, (c,o) => new { c, o }).
OrderByDescending(* => o.Total).
Select(* => new { c.Name, o.Total })
```

which, when transparent identifiers are erased, is equivalent to

```
customers.
SelectMany(c => c.Orders, (c,o) => new { c, o }).
OrderByDescending(x => x.o.Total).
Select(x => new { x.c.Name, x.o.Total })
```

where `x` is a compiler generated identifier that is otherwise invisible and inaccessible.

The example

```
from c in customers
join o in orders on c.CustomerID equals o.CustomerID
join d in details on o.OrderID equals d.OrderID
join p in products on d.ProductID equals p.ProductID
select new { c.Name, o.OrderDate, p.ProductName }
```

is translated into

```
from * in customers.
    Join(orders, c => c.CustomerID, o => o.CustomerID,
        (c, o) => new { c, o })
join d in details on o.OrderID equals d.OrderID
join p in products on d.ProductID equals p.ProductID
select new { c.Name, o.OrderDate, p.ProductName }
```

which is further reduced to

```
customers.
Join(orders, c => c.CustomerID, o => o.CustomerID, (c, o) => new { c, o }).
Join(details, * => o.OrderID, d => d.OrderID, (*, d) => new { *, d }).
Join(products, * => d.ProductID, p => p.ProductID, (*, p) => new { *, p }).
Select(* => new { c.Name, o.OrderDate, p.ProductName })
```

the final translation of which is

```
customers.
Join(orders, c => c.CustomerID, o => o.CustomerID,
    (c, o) => new { c, o }).
Join(details, x => x.o.OrderID, d => d.OrderID,
    (x, d) => new { x, d }).
Join(products, y => y.d.ProductID, p => p.ProductID,
    (y, p) => new { y, p }).
Select(z => new { z.y.x.c.Name, z.y.x.o.OrderDate, z.p.ProductName })
```

where `x`, `y`, and `z` are compiler generated identifiers that are otherwise invisible and inaccessible.

The query expression pattern

The *Query expression pattern* establishes a pattern of methods that types can implement to support query expressions. Because query expressions are translated to method invocations by means of a syntactic mapping, types have considerable flexibility in how they implement the query expression pattern. For example, the

methods of the pattern can be implemented as instance methods or as extension methods because the two have the same invocation syntax, and the methods can request delegates or expression trees because anonymous functions are convertible to both.

The recommended shape of a generic type `C<T>` that supports the query expression pattern is shown below. A generic type is used in order to illustrate the proper relationships between parameter and result types, but it is possible to implement the pattern for non-generic types as well.

```
delegate R Func<T1,R>(T1 arg1);

delegate R Func<T1,T2,R>(T1 arg1, T2 arg2);

class C
{
    public C<T> Cast<T>();
}

class C<T> : C
{
    public C<T> Where(Func<T,bool> predicate);

    public C<U> Select<U>(Func<T,U> selector);

    public C<V> SelectMany<U,V>(Func<T,C<U>> selector,
        Func<T,U,V> resultSelector);

    public C<V> Join<U,K,V>(C<U> inner, Func<T,K> outerKeySelector,
        Func<U,K> innerKeySelector, Func<T,U,V> resultSelector);

    public C<V> GroupJoin<U,K,V>(C<U> inner, Func<T,K> outerKeySelector,
        Func<U,K> innerKeySelector, Func<T,C<U>,V> resultSelector);

    public O<T> OrderBy<K>(Func<T,K> keySelector);

    public O<T> OrderByDescending<K>(Func<T,K> keySelector);

    public C<G<K,T>> GroupBy<K>(Func<T,K> keySelector);

    public C<G<K,E>> GroupBy<K,E>(Func<T,K> keySelector,
        Func<T,E> elementSelector);
}

class O<T> : C<T>
{
    public O<T> ThenBy<K>(Func<T,K> keySelector);

    public O<T> ThenByDescending<K>(Func<T,K> keySelector);
}

class G<K,T> : C<T>
{
    public K Key { get; }
}
```

The methods above use the generic delegate types `Func<T1,R>` and `Func<T1,T2,R>`, but they could equally well have used other delegate or expression tree types with the same relationships in parameter and result types.

Notice the recommended relationship between `C<T>` and `O<T>` which ensures that the `ThenBy` and `ThenByDescending` methods are available only on the result of an `OrderBy` or `OrderByDescending`. Also notice the recommended shape of the result of `GroupBy` -- a sequence of sequences, where each inner sequence has an additional `Key` property.

The `System.Linq` namespace provides an implementation of the query operator pattern for any type that

implements the `System.Collections.Generic.IEnumerable<T>` interface.

Assignment operators

The assignment operators assign a new value to a variable, a property, an event, or an indexer element.

```
assignment
: unary_expression assignment_operator expression
;

assignment_operator
: '='
| '+='
| '-='
| '*='
| '/='
| '%='
| '&='
| '|='
| '^='
| '<<='
| right_shift_assignment
;
```

The left operand of an assignment must be an expression classified as a variable, a property access, an indexer access, or an event access.

The `=` operator is called the *simple assignment operator*. It assigns the value of the right operand to the variable, property, or indexer element given by the left operand. The left operand of the simple assignment operator may not be an event access (except as described in [Field-like events](#)). The simple assignment operator is described in [Simple assignment](#).

The assignment operators other than the `=` operator are called the *compound assignment operators*. These operators perform the indicated operation on the two operands, and then assign the resulting value to the variable, property, or indexer element given by the left operand. The compound assignment operators are described in [Compound assignment](#).

The `+=` and `-=` operators with an event access expression as the left operand are called the *event assignment operators*. No other assignment operator is valid with an event access as the left operand. The event assignment operators are described in [Event assignment](#).

The assignment operators are right-associative, meaning that operations are grouped from right to left. For example, an expression of the form `a = b = c` is evaluated as `a = (b = c)`.

Simple assignment

The `=` operator is called the simple assignment operator.

If the left operand of a simple assignment is of the form `E.P` or `E[Ei]` where `E` has the compile-time type `dynamic`, then the assignment is dynamically bound ([Dynamic binding](#)). In this case the compile-time type of the assignment expression is `dynamic`, and the resolution described below will take place at run-time based on the run-time type of `E`.

In a simple assignment, the right operand must be an expression that is implicitly convertible to the type of the left operand. The operation assigns the value of the right operand to the variable, property, or indexer element given by the left operand.

The result of a simple assignment expression is the value assigned to the left operand. The result has the same type as the left operand and is always classified as a value.

If the left operand is a property or indexer access, the property or indexer must have a `set` accessor. If this is not the case, a binding-time error occurs.

The run-time processing of a simple assignment of the form `x = y` consists of the following steps:

- If `x` is classified as a variable:
 - `x` is evaluated to produce the variable.
 - `y` is evaluated and, if required, converted to the type of `x` through an implicit conversion ([Implicit conversions](#)).
 - If the variable given by `x` is an array element of a *reference_type*, a run-time check is performed to ensure that the value computed for `y` is compatible with the array instance of which `x` is an element. The check succeeds if `y` is `null`, or if an implicit reference conversion ([Implicit reference conversions](#)) exists from the actual type of the instance referenced by `y` to the actual element type of the array instance containing `x`. Otherwise, a `System.ArrayTypeMismatchException` is thrown.
 - The value resulting from the evaluation and conversion of `y` is stored into the location given by the evaluation of `x`.
- If `x` is classified as a property or indexer access:
 - The instance expression (if `x` is not `static`) and the argument list (if `x` is an indexer access) associated with `x` are evaluated, and the results are used in the subsequent `set` accessor invocation.
 - `y` is evaluated and, if required, converted to the type of `x` through an implicit conversion ([Implicit conversions](#)).
 - The `set` accessor of `x` is invoked with the value computed for `y` as its `value` argument.

The array co-variance rules ([Array covariance](#)) permit a value of an array type `A[]` to be a reference to an instance of an array type `B[]`, provided an implicit reference conversion exists from `B` to `A`. Because of these rules, assignment to an array element of a *reference_type* requires a run-time check to ensure that the value being assigned is compatible with the array instance. In the example

```
string[] sa = new string[10];
object[] oa = sa;

oa[0] = null;           // Ok
oa[1] = "Hello";        // Ok
oa[2] = new ArrayList(); // ArrayTypeMismatchException
```

the last assignment causes a `System.ArrayTypeMismatchException` to be thrown because an instance of `ArrayList` cannot be stored in an element of a `string[]`.

When a property or indexer declared in a *struct_type* is the target of an assignment, the instance expression associated with the property or indexer access must be classified as a variable. If the instance expression is classified as a value, a binding-time error occurs. Because of [Member access](#), the same rule also applies to fields.

Given the declarations:

```

struct Point
{
    int x, y;

    public Point(int x, int y) {
        this.x = x;
        this.y = y;
    }

    public int X {
        get { return x; }
        set { x = value; }
    }

    public int Y {
        get { return y; }
        set { y = value; }
    }
}

struct Rectangle
{
    Point a, b;

    public Rectangle(Point a, Point b) {
        this.a = a;
        this.b = b;
    }

    public Point A {
        get { return a; }
        set { a = value; }
    }

    public Point B {
        get { return b; }
        set { b = value; }
    }
}

```

in the example

```

Point p = new Point();
p.X = 100;
p.Y = 100;
Rectangle r = new Rectangle();
r.A = new Point(10, 10);
r.B = p;

```

the assignments to `p.X`, `p.Y`, `r.A`, and `r.B` are permitted because `p` and `r` are variables. However, in the example

```

Rectangle r = new Rectangle();
r.A.X = 10;
r.A.Y = 10;
r.B.X = 100;
r.B.Y = 100;

```

the assignments are all invalid, since `r.A` and `r.B` are not variables.

Compound assignment

If the left operand of a compound assignment is of the form `E.P` or `E[Ei]` where `E` has the compile-time type

`dynamic`, then the assignment is dynamically bound ([Dynamic binding](#)). In this case the compile-time type of the assignment expression is `dynamic`, and the resolution described below will take place at run-time based on the run-time type of `E`.

An operation of the form `x op= y` is processed by applying binary operator overload resolution ([Binary operator overload resolution](#)) as if the operation was written `x op y`. Then,

- If the return type of the selected operator is implicitly convertible to the type of `x`, the operation is evaluated as `x = x op y`, except that `x` is evaluated only once.
- Otherwise, if the selected operator is a predefined operator, if the return type of the selected operator is explicitly convertible to the type of `x`, and if `y` is implicitly convertible to the type of `x` or the operator is a shift operator, then the operation is evaluated as `x = (T)(x op y)`, where `T` is the type of `x`, except that `x` is evaluated only once.
- Otherwise, the compound assignment is invalid, and a binding-time error occurs.

The term "evaluated only once" means that in the evaluation of `x op y`, the results of any constituent expressions of `x` are temporarily saved and then reused when performing the assignment to `x`. For example, in the assignment `A()[B()] += C()`, where `A` is a method returning `int[]`, and `B` and `C` are methods returning `int`, the methods are invoked only once, in the order `A`, `B`, `C`.

When the left operand of a compound assignment is a property access or indexer access, the property or indexer must have both a `get` accessor and a `set` accessor. If this is not the case, a binding-time error occurs.

The second rule above permits `x op= y` to be evaluated as `x = (T)(x op y)` in certain contexts. The rule exists such that the predefined operators can be used as compound operators when the left operand is of type `sbyte`, `byte`, `short`, `ushort`, or `char`. Even when both arguments are of one of those types, the predefined operators produce a result of type `int`, as described in [Binary numeric promotions](#). Thus, without a cast it would not be possible to assign the result to the left operand.

The intuitive effect of the rule for predefined operators is simply that `x op= y` is permitted if both of `x op y` and `x = y` are permitted. In the example

```
byte b = 0;
char ch = '\0';
int i = 0;

b += 1;           // Ok
b += 1000;        // Error, b = 1000 not permitted
b += i;           // Error, b = i not permitted
b += (byte)i;     // Ok

ch += 1;          // Error, ch = 1 not permitted
ch += (char)1;    // Ok
```

the intuitive reason for each error is that a corresponding simple assignment would also have been an error.

This also means that compound assignment operations support lifted operations. In the example

```
int? i = 0;
i += 1;           // Ok
```

the lifted operator `+(int?,int?)` is used.

Event assignment

If the left operand of a `+=` or `-=` operator is classified as an event access, then the expression is evaluated as follows:

- The instance expression, if any, of the event access is evaluated.
- The right operand of the `+=` or `-=` operator is evaluated, and, if required, converted to the type of the left operand through an implicit conversion ([Implicit conversions](#)).
- An event accessor of the event is invoked, with argument list consisting of the right operand, after evaluation and, if necessary, conversion. If the operator was `+=`, the `add` accessor is invoked; if the operator was `-=`, the `remove` accessor is invoked.

An event assignment expression does not yield a value. Thus, an event assignment expression is valid only in the context of a *statement_expression* ([Expression statements](#)).

Expression

An *expression* is either a *non_assignment_expression* or an *assignment*.

```
expression
: non_assignment_expression
| assignment
;

non_assignment_expression
: conditional_expression
| lambda_expression
| query_expression
;
```

Constant expressions

A *constant_expression* is an expression that can be fully evaluated at compile-time.

```
constant_expression
: expression
;
```

A constant expression must be the `null` literal or a value with one of the following types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `float`, `double`, `decimal`, `bool`, `object`, `string`, or any enumeration type. Only the following constructs are permitted in constant expressions:

- Literals (including the `null` literal).
- References to `const` members of class and struct types.
- References to members of enumeration types.
- References to `const` parameters or local variables
- Parenthesized sub-expressions, which are themselves constant expressions.
- Cast expressions, provided the target type is one of the types listed above.
- `checked` and `unchecked` expressions
- Default value expressions
- Nameof expressions
- The predefined `+`, `-`, `!`, and `~` unary operators.
- The predefined `+`, `-`, `*`, `/`, `%`, `<<`, `>>`, `&`, `|`, `^`, `&&`, `||`, `==`, `!=`, `<`, `>`, `<=`, and `>=` binary operators, provided each operand is of a type listed above.
- The `?:` conditional operator.

The following conversions are permitted in constant expressions:

- Identity conversions
- Numeric conversions
- Enumeration conversions
- Constant expression conversions
- Implicit and explicit reference conversions, provided that the source of the conversions is a constant expression that evaluates to the null value.

Other conversions including boxing, unboxing and implicit reference conversions of non-null values are not permitted in constant expressions. For example:

```
class C {
    const object i = 5;           // error: boxing conversion not permitted
    const object str = "hello"; // error: implicit reference conversion
}
```

the initialization of `i` is an error because a boxing conversion is required. The initialization of `str` is an error because an implicit reference conversion from a non-null value is required.

Whenever an expression fulfills the requirements listed above, the expression is evaluated at compile-time. This is true even if the expression is a sub-expression of a larger expression that contains non-constant constructs.

The compile-time evaluation of constant expressions uses the same rules as run-time evaluation of non-constant expressions, except that where run-time evaluation would have thrown an exception, compile-time evaluation causes a compile-time error to occur.

Unless a constant expression is explicitly placed in an `unchecked` context, overflows that occur in integral-type arithmetic operations and conversions during the compile-time evaluation of the expression always cause compile-time errors ([Constant expressions](#)).

Constant expressions occur in the contexts listed below. In these contexts, a compile-time error occurs if an expression cannot be fully evaluated at compile-time.

- Constant declarations ([Constants](#)).
- Enumeration member declarations ([Enum members](#)).
- Default arguments of formal parameter lists ([Method parameters](#))
- `case` labels of a `switch` statement ([The switch statement](#)).
- `goto case` statements ([The goto statement](#)).
- Dimension lengths in an array creation expression ([Array creation expressions](#)) that includes an initializer.
- Attributes ([Attributes](#)).

An implicit constant expression conversion ([Implicit constant expression conversions](#)) permits a constant expression of type `int` to be converted to `sbyte`, `byte`, `short`, `ushort`, `uint`, or `ulong`, provided the value of the constant expression is within the range of the destination type.

Boolean expressions

A *boolean_expression* is an expression that yields a result of type `bool`; either directly or through application of `operator true` in certain contexts as specified in the following.

```
boolean_expression
: expression
;
```

The controlling conditional expression of an *if_statement* ([The if statement](#)), *while_statement* ([The while](#)

[statement](#)), *do_statement* ([The do statement](#)), or *for_statement* ([The for statement](#)) is a *boolean_expression*. The controlling conditional expression of the `?:` operator ([Conditional operator](#)) follows the same rules as a *boolean_expression*, but for reasons of operator precedence is classified as a *conditional_or_expression*.

A *boolean_expression* `E` is required to be able to produce a value of type `bool`, as follows:

- If `E` is implicitly convertible to `bool` then at runtime that implicit conversion is applied.
- Otherwise, unary operator overload resolution ([Unary operator overload resolution](#)) is used to find a unique best implementation of operator `true` on `E`, and that implementation is applied at runtime.
- If no such operator is found, a binding-time error occurs.

The `DBBbool` struct type in [Database boolean type](#) provides an example of a type that implements `operator true` and `operator false`.

Statements

12/28/2021 • 54 minutes to read • [Edit Online](#)

C# provides a variety of statements. Most of these statements will be familiar to developers who have programmed in C and C++.

```
statement
: labeled_statement
| declaration_statement
| embedded_statement
;

embedded_statement
: block
| empty_statement
| expression_statement
| selection_statement
| iteration_statement
| jump_statement
| try_statement
| checked_statement
| unchecked_statement
| lock_statement
| using_statement
| yield_statement
| embedded_statement_unsafe
;
```

The *embedded_statement* nonterminal is used for statements that appear within other statements. The use of *embedded_statement* rather than *statement* excludes the use of declaration statements and labeled statements in these contexts. The example

```
void F(bool b) {
    if (b)
        int i = 44;
}
```

results in a compile-time error because an `if` statement requires an *embedded_statement* rather than a *statement* for its if branch. If this code were permitted, then the variable `i` would be declared, but it could never be used. Note, however, that by placing `i`'s declaration in a block, the example is valid.

End points and reachability

Every statement has an *end point*. In intuitive terms, the end point of a statement is the location that immediately follows the statement. The execution rules for composite statements (statements that contain embedded statements) specify the action that is taken when control reaches the end point of an embedded statement. For example, when control reaches the end point of a statement in a block, control is transferred to the next statement in the block.

If a statement can possibly be reached by execution, the statement is said to be *reachable*. Conversely, if there is no possibility that a statement will be executed, the statement is said to be *unreachable*.

In the example

```
void F() {
    Console.WriteLine("reachable");
    goto Label;
    Console.WriteLine("unreachable");
Label:
    Console.WriteLine("reachable");
}
```

the second invocation of `Console.WriteLine` is unreachable because there is no possibility that the statement will be executed.

A warning is reported if the compiler determines that a statement is unreachable. It is specifically not an error for a statement to be unreachable.

To determine whether a particular statement or end point is reachable, the compiler performs flow analysis according to the reachability rules defined for each statement. The flow analysis takes into account the values of constant expressions ([Constant expressions](#)) that control the behavior of statements, but the possible values of non-constant expressions are not considered. In other words, for purposes of control flow analysis, a non-constant expression of a given type is considered to have any possible value of that type.

In the example

```
void F() {
    const int i = 1;
    if (i == 2) Console.WriteLine("unreachable");
}
```

the boolean expression of the `if` statement is a constant expression because both operands of the `==` operator are constants. As the constant expression is evaluated at compile-time, producing the value `false`, the `Console.WriteLine` invocation is considered unreachable. However, if `i` is changed to be a local variable

```
void F() {
    int i = 1;
    if (i == 2) Console.WriteLine("reachable");
}
```

the `Console.WriteLine` invocation is considered reachable, even though, in reality, it will never be executed.

The *block* of a function member is always considered reachable. By successively evaluating the reachability rules of each statement in a block, the reachability of any given statement can be determined.

In the example

```
void F(int x) {
    Console.WriteLine("start");
    if (x < 0) Console.WriteLine("negative");
}
```

the reachability of the second `Console.WriteLine` is determined as follows:

- The first `Console.WriteLine` expression statement is reachable because the block of the `F` method is reachable.
- The end point of the first `Console.WriteLine` expression statement is reachable because that statement is reachable.
- The `if` statement is reachable because the end point of the first `Console.WriteLine` expression statement is reachable.

- The second `Console.WriteLine` expression statement is reachable because the boolean expression of the `if` statement does not have the constant value `false`.

There are two situations in which it is a compile-time error for the end point of a statement to be reachable:

- Because the `switch` statement does not permit a switch section to "fall through" to the next switch section, it is a compile-time error for the end point of the statement list of a switch section to be reachable. If this error occurs, it is typically an indication that a `break` statement is missing.
- It is a compile-time error for the end point of the block of a function member that computes a value to be reachable. If this error occurs, it typically is an indication that a `return` statement is missing.

Blocks

A *block* permits multiple statements to be written in contexts where a single statement is allowed.

```
block
    : '{' statement_list? '}'
    ;
```

A *block* consists of an optional *statement_list* ([Statement lists](#)), enclosed in braces. If the statement list is omitted, the block is said to be empty.

A block may contain declaration statements ([Declaration statements](#)). The scope of a local variable or constant declared in a block is the block.

A block is executed as follows:

- If the block is empty, control is transferred to the end point of the block.
- If the block is not empty, control is transferred to the statement list. When and if control reaches the end point of the statement list, control is transferred to the end point of the block.

The statement list of a block is reachable if the block itself is reachable.

The end point of a block is reachable if the block is empty or if the end point of the statement list is reachable.

A *block* that contains one or more `yield` statements ([The yield statement](#)) is called an iterator block. Iterator blocks are used to implement function members as iterators ([Iterators](#)). Some additional restrictions apply to iterator blocks:

- It is a compile-time error for a `return` statement to appear in an iterator block (but `yield return` statements are permitted).
- It is a compile-time error for an iterator block to contain an unsafe context ([Unsafe contexts](#)). An iterator block always defines a safe context, even when its declaration is nested in an unsafe context.

Statement lists

A ***statement list*** consists of one or more statements written in sequence. Statement lists occur in *blocks* ([Blocks](#)) and in *switch_blocks* ([The switch statement](#)).

```
statement_list
    : statement+
    ;
```

A statement list is executed by transferring control to the first statement. When and if control reaches the end point of a statement, control is transferred to the next statement. When and if control reaches the end point of the last statement, control is transferred to the end point of the statement list.

A statement in a statement list is reachable if at least one of the following is true:

- The statement is the first statement and the statement list itself is reachable.
- The end point of the preceding statement is reachable.
- The statement is a labeled statement and the label is referenced by a reachable `goto` statement.

The end point of a statement list is reachable if the end point of the last statement in the list is reachable.

The empty statement

An *empty_statement* does nothing.

```
empty_statement
: ';'
;
```

An empty statement is used when there are no operations to perform in a context where a statement is required.

Execution of an empty statement simply transfers control to the end point of the statement. Thus, the end point of an empty statement is reachable if the empty statement is reachable.

An empty statement can be used when writing a `while` statement with a null body:

```
bool ProcessMessage() {...}

void ProcessMessages() {
    while (ProcessMessage())
        ;
}
```

Also, an empty statement can be used to declare a label just before the closing "`}`" of a block:

```
void F() {
    ...
    if (done) goto exit;
    ...
    exit: ;
}
```

Labeled statements

A *labeled_statement* permits a statement to be prefixed by a label. Labeled statements are permitted in blocks, but are not permitted as embedded statements.

```
labeled_statement
: identifier ':' statement
;
```

A labeled statement declares a label with the name given by the *identifier*. The scope of a label is the whole block in which the label is declared, including any nested blocks. It is a compile-time error for two labels with the same name to have overlapping scopes.

A label can be referenced from `goto` statements ([The goto statement](#)) within the scope of the label. This means that `goto` statements can transfer control within blocks and out of blocks, but never into blocks.

Labels have their own declaration space and do not interfere with other identifiers. The example

```
int F(int x) {
    if (x >= 0) goto x;
    x = -x;
    x: return x;
}
```

is valid and uses the name `x` as both a parameter and a label.

Execution of a labeled statement corresponds exactly to execution of the statement following the label.

In addition to the reachability provided by normal flow of control, a labeled statement is reachable if the label is referenced by a reachable `goto` statement. (Exception: If a `goto` statement is inside a `try` that includes a `finally` block, and the labeled statement is outside the `try`, and the end point of the `finally` block is unreachable, then the labeled statement is not reachable from that `goto` statement.)

Declaration statements

A *declaration_statement* declares a local variable or constant. Declaration statements are permitted in blocks, but are not permitted as embedded statements.

```
declaration_statement
: local_variable_declaration ';'
| local_constant_declaration ';'
;
```

Local variable declarations

A *local_variable_declaration* declares one or more local variables.

```
local_variable_declaration
: local_variable_type local_variable_declarators
;

local_variable_type
: type
| 'var'
;

local_variable_declarators
: local_variable_declarator
| local_variable_declarators ',' local_variable_declarator
;

local_variable_declarator
: identifier
| identifier '=' local_variable_initializer
;

local_variable_initializer
: expression
| array_initializer
| local_variable_initializer_unsafe
;
```

The *local_variable_type* of a *local_variable_declaration* either directly specifies the type of the variables introduced by the declaration, or indicates with the identifier `var` that the type should be inferred based on an initializer. The type is followed by a list of *local_variable_declarators*, each of which introduces a new variable. A *local_variable_declarator* consists of an *identifier* that names the variable, optionally followed by an `=` token and a *local_variable_initializer* that gives the initial value of the variable.

In the context of a local variable declaration, the identifier `var` acts as a contextual keyword ([Keywords](#)). When the *local_variable_type* is specified as `var` and no type named `var` is in scope, the declaration is an **implicitly typed local variable declaration**, whose type is inferred from the type of the associated initializer expression. Implicitly typed local variable declarations are subject to the following restrictions:

- The *local_variable_declaration* cannot include multiple *local_variable_declarators*.
- The *local_variable_declarator* must include a *local_variable_initializer*.
- The *local_variable_initializer* must be an *expression*.
- The initializer *expression* must have a compile-time type.
- The initializer *expression* cannot refer to the declared variable itself

The following are examples of incorrect implicitly typed local variable declarations:

```
var x;           // Error, no initializer to infer type from
var y = {1, 2, 3}; // Error, array initializer not permitted
var z = null;    // Error, null does not have a type
var u = x => x + 1; // Error, anonymous functions do not have a type
var v = v++;     // Error, initializer cannot refer to variable itself
```

The value of a local variable is obtained in an expression using a *simple_name* ([Simple names](#)), and the value of a local variable is modified using an *assignment* ([Assignment operators](#)). A local variable must be definitely assigned ([Definite assignment](#)) at each location where its value is obtained.

The scope of a local variable declared in a *local_variable_declaration* is the block in which the declaration occurs. It is an error to refer to a local variable in a textual position that precedes the *local_variable_declarator* of the local variable. Within the scope of a local variable, it is a compile-time error to declare another local variable or constant with the same name.

A local variable declaration that declares multiple variables is equivalent to multiple declarations of single variables with the same type. Furthermore, a variable initializer in a local variable declaration corresponds exactly to an assignment statement that is inserted immediately after the declaration.

The example

```
void F() {
    int x = 1, y, z = x * 2;
}
```

corresponds exactly to

```
void F() {
    int x; x = 1;
    int y;
    int z; z = x * 2;
}
```

In an implicitly typed local variable declaration, the type of the local variable being declared is taken to be the same as the type of the expression used to initialize the variable. For example:

```
var i = 5;
var s = "Hello";
var d = 1.0;
var numbers = new int[] {1, 2, 3};
var orders = new Dictionary<int, Order>();
```

The implicitly typed local variable declarations above are precisely equivalent to the following explicitly typed declarations:

```
int i = 5;
string s = "Hello";
double d = 1.0;
int[] numbers = new int[] {1, 2, 3};
Dictionary<int,Order> orders = new Dictionary<int,Order>();
```

Local constant declarations

A *local_constant_declaration* declares one or more local constants.

```
local_constant_declaration
    : 'const' type constant_declarators
    ;

constant_declarators
    : constant_declarator (',' constant_declarator)*
    ;

constant_declarator
    : identifier '=' constant_expression
    ;
```

The *type* of a *local_constant_declaration* specifies the type of the constants introduced by the declaration. The type is followed by a list of *constant_declarators*, each of which introduces a new constant. A *constant_declarator* consists of an *identifier* that names the constant, followed by an "=" token, followed by a *constant_expression* ([Constant expressions](#)) that gives the value of the constant.

The *type* and *constant_expression* of a local constant declaration must follow the same rules as those of a constant member declaration ([Constants](#)).

The value of a local constant is obtained in an expression using a *simple_name* ([Simple names](#)).

The scope of a local constant is the block in which the declaration occurs. It is an error to refer to a local constant in a textual position that precedes its *constant_declarator*. Within the scope of a local constant, it is a compile-time error to declare another local variable or constant with the same name.

A local constant declaration that declares multiple constants is equivalent to multiple declarations of single constants with the same type.

Expression statements

An *expression_statement* evaluates a given expression. The value computed by the expression, if any, is discarded.

```

expression_statement
: statement_expression ';'
;

statement_expression
: invocation_expression
| null_conditional_invocation_expression
| object_creation_expression
| assignment
| post_increment_expression
| post_decrement_expression
| pre_increment_expression
| pre_decrement_expression
| await_expression
;

```

Not all expressions are permitted as statements. In particular, expressions such as `x + y` and `x == 1` that merely compute a value (which will be discarded), are not permitted as statements.

Execution of an *expression_statement* evaluates the contained expression and then transfers control to the end point of the *expression_statement*. The end point of an *expression_statement* is reachable if that *expression_statement* is reachable.

Selection statements

Selection statements select one of a number of possible statements for execution based on the value of some expression.

```

selection_statement
: if_statement
| switch_statement
;

```

The if statement

The `if` statement selects a statement for execution based on the value of a boolean expression.

```

if_statement
: 'if' '(' boolean_expression ')' embedded_statement
| 'if' '(' boolean_expression ')' embedded_statement 'else' embedded_statement
;

```

An `else` part is associated with the lexically nearest preceding `if` that is allowed by the syntax. Thus, an `if` statement of the form

```
if (x) if (y) F(); else G();
```

is equivalent to

```

if (x) {
    if (y) {
        F();
    }
    else {
        G();
    }
}

```

An `if` statement is executed as follows:

- The *boolean_expression* ([Boolean expressions](#)) is evaluated.
- If the boolean expression yields `true`, control is transferred to the first embedded statement. When and if control reaches the end point of that statement, control is transferred to the end point of the `if` statement.
- If the boolean expression yields `false` and if an `else` part is present, control is transferred to the second embedded statement. When and if control reaches the end point of that statement, control is transferred to the end point of the `if` statement.
- If the boolean expression yields `false` and if an `else` part is not present, control is transferred to the end point of the `if` statement.

The first embedded statement of an `if` statement is reachable if the `if` statement is reachable and the boolean expression does not have the constant value `false`.

The second embedded statement of an `if` statement, if present, is reachable if the `if` statement is reachable and the boolean expression does not have the constant value `true`.

The end point of an `if` statement is reachable if the end point of at least one of its embedded statements is reachable. In addition, the end point of an `if` statement with no `else` part is reachable if the `if` statement is reachable and the boolean expression does not have the constant value `true`.

The switch statement

The switch statement selects for execution a statement list having an associated switch label that corresponds to the value of the switch expression.

```
switch_statement
: 'switch' '(' expression ')' switch_block
;

switch_block
: '{' switch_section* '}'
;

switch_section
: switch_label+ statement_list
;

switch_label
: 'case' constant_expression ':'
| 'default' ':'
;
```

A *switch_statement* consists of the keyword `switch`, followed by a parenthesized expression (called the switch expression), followed by a *switch_block*. The *switch_block* consists of zero or more *switch_sections*, enclosed in braces. Each *switch_section* consists of one or more *switch_labels* followed by a *statement_list* ([Statement lists](#)).

The *governing type* of a `switch` statement is established by the switch expression.

- If the type of the switch expression is `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `bool`, `char`, `string`, or an *enum_type*, or if it is the nullable type corresponding to one of these types, then that is the governing type of the `switch` statement.
- Otherwise, exactly one user-defined implicit conversion ([User-defined conversions](#)) must exist from the type of the switch expression to one of the following possible governing types: `sbyte`, `byte`, `short`, `ushort`, `int`, `uint`, `long`, `ulong`, `char`, `string`, or, a nullable type corresponding to one of those types.
- Otherwise, if no such implicit conversion exists, or if more than one such implicit conversion exists, a compile-time error occurs.

The constant expression of each `case` label must denote a value that is implicitly convertible ([Implicit conversions](#)) to the governing type of the `switch` statement. A compile-time error occurs if two or more `case` labels in the same `switch` statement specify the same constant value.

There can be at most one `default` label in a switch statement.

A `switch` statement is executed as follows:

- The switch expression is evaluated and converted to the governing type.
- If one of the constants specified in a `case` label in the same `switch` statement is equal to the value of the switch expression, control is transferred to the statement list following the matched `case` label.
- If none of the constants specified in `case` labels in the same `switch` statement is equal to the value of the switch expression, and if a `default` label is present, control is transferred to the statement list following the `default` label.
- If none of the constants specified in `case` labels in the same `switch` statement is equal to the value of the switch expression, and if no `default` label is present, control is transferred to the end point of the `switch` statement.

If the end point of the statement list of a switch section is reachable, a compile-time error occurs. This is known as the "no fall through" rule. The example

```
switch (i) {  
  case 0:  
    CaseZero();  
    break;  
  case 1:  
    CaseOne();  
    break;  
  default:  
    CaseOthers();  
    break;  
}
```

is valid because no switch section has a reachable end point. Unlike C and C++, execution of a switch section is not permitted to "fall through" to the next switch section, and the example

```
switch (i) {  
  case 0:  
    CaseZero();  
  case 1:  
    CaseZeroOrOne();  
  default:  
    CaseAny();  
}
```

results in a compile-time error. When execution of a switch section is to be followed by execution of another switch section, an explicit `goto case` or `goto default` statement must be used:

```

switch (i) {
case 0:
    CaseZero();
    goto case 1;
case 1:
    CaseZeroOrOne();
    goto default;
default:
    CaseAny();
    break;
}

```

Multiple labels are permitted in a *switch_section*. The example

```

switch (i) {
case 0:
    CaseZero();
    break;
case 1:
    CaseOne();
    break;
case 2:
default:
    CaseTwo();
    break;
}

```

is valid. The example does not violate the "no fall through" rule because the labels `case 2:` and `default:` are part of the same *switch_section*.

The "no fall through" rule prevents a common class of bugs that occur in C and C++ when `break` statements are accidentally omitted. In addition, because of this rule, the switch sections of a `switch` statement can be arbitrarily rearranged without affecting the behavior of the statement. For example, the sections of the `switch` statement above can be reversed without affecting the behavior of the statement:

```

switch (i) {
default:
    CaseAny();
    break;
case 1:
    CaseZeroOrOne();
    goto default;
case 0:
    CaseZero();
    goto case 1;
}

```

The statement list of a switch section typically ends in a `break`, `goto case`, or `goto default` statement, but any construct that renders the end point of the statement list unreachable is permitted. For example, a `while` statement controlled by the boolean expression `true` is known to never reach its end point. Likewise, a `throw` or `return` statement always transfers control elsewhere and never reaches its end point. Thus, the following example is valid:

```

switch (i) {
case 0:
    while (true) F();
case 1:
    throw new ArgumentException();
case 2:
    return;
}

```

The governing type of a `switch` statement may be the type `string`. For example:

```

void DoCommand(string command) {
    switch (command.ToLower()) {
case "run":
    DoRun();
    break;
case "save":
    DoSave();
    break;
case "quit":
    DoQuit();
    break;
default:
    InvalidCommand(command);
    break;
    }
}

```

Like the string equality operators ([String equality operators](#)), the `switch` statement is case sensitive and will execute a given switch section only if the switch expression string exactly matches a `case` label constant.

When the governing type of a `switch` statement is `string`, the value `null` is permitted as a case label constant.

The *statement_lists* of a *switch_block* may contain declaration statements ([Declaration statements](#)). The scope of a local variable or constant declared in a switch block is the switch block.

The statement list of a given switch section is reachable if the `switch` statement is reachable and at least one of the following is true:

- The switch expression is a non-constant value.
- The switch expression is a constant value that matches a `case` label in the switch section.
- The switch expression is a constant value that doesn't match any `case` label, and the switch section contains the `default` label.
- A switch label of the switch section is referenced by a reachable `goto case` or `goto default` statement.

The end point of a `switch` statement is reachable if at least one of the following is true:

- The `switch` statement contains a reachable `break` statement that exits the `switch` statement.
- The `switch` statement is reachable, the switch expression is a non-constant value, and no `default` label is present.
- The `switch` statement is reachable, the switch expression is a constant value that doesn't match any `case` label, and no `default` label is present.

Iteration statements

Iteration statements repeatedly execute an embedded statement.

```
iteration_statement
: while_statement
| do_statement
| for_statement
| foreach_statement
;
```

The while statement

The `while` statement conditionally executes an embedded statement zero or more times.

```
while_statement
: 'while' '(' boolean_expression ')' embedded_statement
;
```

A `while` statement is executed as follows:

- The *boolean_expression* ([Boolean expressions](#)) is evaluated.
- If the boolean expression yields `true`, control is transferred to the embedded statement. When and if control reaches the end point of the embedded statement (possibly from execution of a `continue` statement), control is transferred to the beginning of the `while` statement.
- If the boolean expression yields `false`, control is transferred to the end point of the `while` statement.

Within the embedded statement of a `while` statement, a `break` statement ([The break statement](#)) may be used to transfer control to the end point of the `while` statement (thus ending iteration of the embedded statement), and a `continue` statement ([The continue statement](#)) may be used to transfer control to the end point of the embedded statement (thus performing another iteration of the `while` statement).

The embedded statement of a `while` statement is reachable if the `while` statement is reachable and the boolean expression does not have the constant value `false`.

The end point of a `while` statement is reachable if at least one of the following is true:

- The `while` statement contains a reachable `break` statement that exits the `while` statement.
- The `while` statement is reachable and the boolean expression does not have the constant value `true`.

The do statement

The `do` statement conditionally executes an embedded statement one or more times.

```
do_statement
: 'do' embedded_statement 'while' '(' boolean_expression ')' ';'
;
```

A `do` statement is executed as follows:

- Control is transferred to the embedded statement.
- When and if control reaches the end point of the embedded statement (possibly from execution of a `continue` statement), the *boolean_expression* ([Boolean expressions](#)) is evaluated. If the boolean expression yields `true`, control is transferred to the beginning of the `do` statement. Otherwise, control is transferred to the end point of the `do` statement.

Within the embedded statement of a `do` statement, a `break` statement ([The break statement](#)) may be used to transfer control to the end point of the `do` statement (thus ending iteration of the embedded statement), and a `continue` statement ([The continue statement](#)) may be used to transfer control to the end point of the embedded statement.

The embedded statement of a `do` statement is reachable if the `do` statement is reachable.

The end point of a `do` statement is reachable if at least one of the following is true:

- The `do` statement contains a reachable `break` statement that exits the `do` statement.
- The end point of the embedded statement is reachable and the boolean expression does not have the constant value `true`.

The for statement

The `for` statement evaluates a sequence of initialization expressions and then, while a condition is true, repeatedly executes an embedded statement and evaluates a sequence of iteration expressions.

```
for_statement
: 'for' '(' for_initializer? ';' for_condition? ';' for_iterator? ')' embedded_statement
;

for_initializer
: local_variable_declaration
| statement_expression_list
;

for_condition
: boolean_expression
;

for_iterator
: statement_expression_list
;

statement_expression_list
: statement_expression (',' statement_expression)*
;
```

The *for_initializer*, if present, consists of either a *local_variable_declaration* ([Local variable declarations](#)) or a list of *statement_expressions* ([Expression statements](#)) separated by commas. The scope of a local variable declared by a *for_initializer* starts at the *local_variable_declarator* for the variable and extends to the end of the embedded statement. The scope includes the *for_condition* and the *for_iterator*.

The *for_condition*, if present, must be a *boolean_expression* ([Boolean expressions](#)).

The *for_iterator*, if present, consists of a list of *statement_expressions* ([Expression statements](#)) separated by commas.

A for statement is executed as follows:

- If a *for_initializer* is present, the variable initializers or statement expressions are executed in the order they are written. This step is only performed once.
- If a *for_condition* is present, it is evaluated.
- If the *for_condition* is not present or if the evaluation yields `true`, control is transferred to the embedded statement. When and if control reaches the end point of the embedded statement (possibly from execution of a `continue` statement), the expressions of the *for_iterator*, if any, are evaluated in sequence, and then another iteration is performed, starting with evaluation of the *for_condition* in the step above.
- If the *for_condition* is present and the evaluation yields `false`, control is transferred to the end point of the `for` statement.

Within the embedded statement of a `for` statement, a `break` statement ([The break statement](#)) may be used to transfer control to the end point of the `for` statement (thus ending iteration of the embedded statement), and a `continue` statement ([The continue statement](#)) may be used to transfer control to the end point of the embedded

statement (thus executing the *for_iterator* and performing another iteration of the `for` statement, starting with the *for_condition*).

The embedded statement of a `for` statement is reachable if one of the following is true:

- The `for` statement is reachable and no *for_condition* is present.
- The `for` statement is reachable and a *for_condition* is present and does not have the constant value `false`.

The end point of a `for` statement is reachable if at least one of the following is true:

- The `for` statement contains a reachable `break` statement that exits the `for` statement.
- The `for` statement is reachable and a *for_condition* is present and does not have the constant value `true`.

The foreach statement

The `foreach` statement enumerates the elements of a collection, executing an embedded statement for each element of the collection.

```
foreach_statement
: 'foreach' '(' local_variable_type identifier 'in' expression ')' embedded_statement
;
```

The *type* and *identifier* of a `foreach` statement declare the **iteration variable** of the statement. If the `var` identifier is given as the *local_variable_type*, and no type named `var` is in scope, the iteration variable is said to be an **implicitly typed iteration variable**, and its type is taken to be the element type of the `foreach` statement, as specified below. The iteration variable corresponds to a read-only local variable with a scope that extends over the embedded statement. During execution of a `foreach` statement, the iteration variable represents the collection element for which an iteration is currently being performed. A compile-time error occurs if the embedded statement attempts to modify the iteration variable (via assignment or the `++` and `--` operators) or pass the iteration variable as a `ref` or `out` parameter.

In the following, for brevity, `IEnumerable`, `IEnumerator`, `IEnumerable<T>` and `IEnumerator<T>` refer to the corresponding types in the namespaces `System.Collections` and `System.Collections.Generic`.

The compile-time processing of a `foreach` statement first determines the **collection type**, **enumerator type** and **element type** of the expression. This determination proceeds as follows:

- If the type `x` of *expression* is an array type then there is an implicit reference conversion from `x` to the `IEnumerable` interface (since `System.Array` implements this interface). The **collection type** is the `IEnumerable` interface, the **enumerator type** is the `IEnumerator` interface and the **element type** is the element type of the array type `x`.
- If the type `x` of *expression* is `dynamic` then there is an implicit conversion from *expression* to the `IEnumerable` interface ([Implicit dynamic conversions](#)). The **collection type** is the `IEnumerable` interface and the **enumerator type** is the `IEnumerator` interface. If the `var` identifier is given as the *local_variable_type* then the **element type** is `dynamic`, otherwise it is `object`.
- Otherwise, determine whether the type `x` has an appropriate `GetEnumerator` method:
 - Perform member lookup on the type `x` with identifier `GetEnumerator` and no type arguments. If the member lookup does not produce a match, or it produces an ambiguity, or produces a match that is not a method group, check for an enumerable interface as described below. It is recommended that a warning be issued if member lookup produces anything except a method group or no match.
 - Perform overload resolution using the resulting method group and an empty argument list. If overload resolution results in no applicable methods, results in an ambiguity, or results in a single best method but that method is either static or not public, check for an enumerable interface as described

below. It is recommended that a warning be issued if overload resolution produces anything except an unambiguous public instance method or no applicable methods.

- If the return type `E` of the `GetEnumerator` method is not a class, struct or interface type, an error is produced and no further steps are taken.
- Member lookup is performed on `E` with the identifier `Current` and no type arguments. If the member lookup produces no match, the result is an error, or the result is anything except a public instance property that permits reading, an error is produced and no further steps are taken.
- Member lookup is performed on `E` with the identifier `MoveNext` and no type arguments. If the member lookup produces no match, the result is an error, or the result is anything except a method group, an error is produced and no further steps are taken.
- Overload resolution is performed on the method group with an empty argument list. If overload resolution results in no applicable methods, results in an ambiguity, or results in a single best method but that method is either static or not public, or its return type is not `bool`, an error is produced and no further steps are taken.
- The *collection type* is `X`, the *enumerator type* is `E`, and the *element type* is the type of the `Current` property.
- Otherwise, check for an enumerable interface:
 - If among all the types `Ti` for which there is an implicit conversion from `X` to `IEnumerable<Ti>`, there is a unique type `T` such that `T` is not `dynamic` and for all the other `Ti` there is an implicit conversion from `IEnumerable<T>` to `IEnumerable<Ti>`, then the *collection type* is the interface `IEnumerable<T>`, the *enumerator type* is the interface `IEnumerator<T>`, and the *element type* is `T`.
 - Otherwise, if there is more than one such type `T`, then an error is produced and no further steps are taken.
 - Otherwise, if there is an implicit conversion from `X` to the `System.Collections.IEnumerable` interface, then the *collection type* is this interface, the *enumerator type* is the interface `System.Collections.IEnumerator`, and the *element type* is `object`.
 - Otherwise, an error is produced and no further steps are taken.

The above steps, if successful, unambiguously produce a collection type `C`, enumerator type `E` and element type `T`. A `foreach` statement of the form

```
foreach (V v in x) embedded_statement
```

is then expanded to:

```
{
    E e = ((C)(x)).GetEnumerator();
    try {
        while (e.MoveNext()) {
            V v = (V)(T)e.Current;
            embedded_statement
        }
    }
    finally {
        ... // Dispose e
    }
}
```

The variable `e` is not visible to or accessible to the expression `x` or the embedded statement or any other source code of the program. The variable `v` is read-only in the embedded statement. If there is not an explicit conversion ([Explicit conversions](#)) from `T` (the element type) to `V` (the *local_variable_type* in the `foreach` statement), an error is produced and no further steps are taken. If `x` has the value `null`, a

`System.NullReferenceException` is thrown at run-time.

An implementation is permitted to implement a given foreach-statement differently, e.g. for performance reasons, as long as the behavior is consistent with the above expansion.

The placement of `v` inside the while loop is important for how it is captured by any anonymous function occurring in the *embedded_statement*.

For example:

```
int[] values = { 7, 9, 13 };
Action f = null;

foreach (var value in values)
{
    if (f == null) f = () => Console.WriteLine("First value: " + value);
}

f();
```

If `v` was declared outside of the while loop, it would be shared among all iterations, and its value after the for loop would be the final value, `13`, which is what the invocation of `f` would print. Instead, because each iteration has its own variable `v`, the one captured by `f` in the first iteration will continue to hold the value `7`, which is what will be printed. (Note: earlier versions of C# declared `v` outside of the while loop.)

The body of the finally block is constructed according to the following steps:

- If there is an implicit conversion from `E` to the `System.IDisposable` interface, then
 - If `E` is a non-nullable value type then the finally clause is expanded to the semantic equivalent of:

```
finally {
    ((System.IDisposable)e).Dispose();
}
```

- Otherwise the finally clause is expanded to the semantic equivalent of:

```
finally {
    if (e != null) ((System.IDisposable)e).Dispose();
}
```

except that if `E` is a value type, or a type parameter instantiated to a value type, then the cast of `e` to `System.IDisposable` will not cause boxing to occur.

- Otherwise, if `E` is a sealed type, the finally clause is expanded to an empty block:

```
finally {
}
```

- Otherwise, the finally clause is expanded to:

```
finally {
    System.IDisposable d = e as System.IDisposable;
    if (d != null) d.Dispose();
}
```

The local variable `d` is not visible to or accessible to any user code. In particular, it does not conflict with any other variable whose scope includes the finally block.

The order in which `foreach` traverses the elements of an array, is as follows: For single-dimensional arrays elements are traversed in increasing index order, starting with index `0` and ending with index `Length - 1`. For multi-dimensional arrays, elements are traversed such that the indices of the rightmost dimension are increased first, then the next left dimension, and so on to the left.

The following example prints out each value in a two-dimensional array, in element order:

```
using System;

class Test
{
    static void Main() {
        double[,] values = {
            {1.2, 2.3, 3.4, 4.5},
            {5.6, 6.7, 7.8, 8.9}
        };

        foreach (double elementValue in values)
            Console.Write("{0} ", elementValue);

        Console.WriteLine();
    }
}
```

The output produced is as follows:

```
1.2 2.3 3.4 4.5 5.6 6.7 7.8 8.9
```

In the example

```
int[] numbers = { 1, 3, 5, 7, 9 };
foreach (var n in numbers) Console.WriteLine(n);
```

the type of `n` is inferred to be `int`, the element type of `numbers`.

Jump statements

Jump statements unconditionally transfer control.

```
jump_statement
: break_statement
| continue_statement
| goto_statement
| return_statement
| throw_statement
;
```

The location to which a jump statement transfers control is called the *target* of the jump statement.

When a jump statement occurs within a block, and the target of that jump statement is outside that block, the jump statement is said to *exit* the block. While a jump statement may transfer control out of a block, it can never transfer control into a block.

Execution of jump statements is complicated by the presence of intervening `try` statements. In the absence of

such `try` statements, a jump statement unconditionally transfers control from the jump statement to its target. In the presence of such intervening `try` statements, execution is more complex. If the jump statement exits one or more `try` blocks with associated `finally` blocks, control is initially transferred to the `finally` block of the innermost `try` statement. When and if control reaches the end point of a `finally` block, control is transferred to the `finally` block of the next enclosing `try` statement. This process is repeated until the `finally` blocks of all intervening `try` statements have been executed.

In the example

```
using System;

class Test
{
    static void Main() {
        while (true) {
            try {
                try {
                    Console.WriteLine("Before break");
                    break;
                }
                finally {
                    Console.WriteLine("Innermost finally block");
                }
            }
            finally {
                Console.WriteLine("Outermost finally block");
            }
        }
        Console.WriteLine("After break");
    }
}
```

the `finally` blocks associated with two `try` statements are executed before control is transferred to the target of the jump statement.

The output produced is as follows:

```
Before break
Innermost finally block
Outermost finally block
After break
```

The break statement

The `break` statement exits the nearest enclosing `switch`, `while`, `do`, `for`, or `foreach` statement.

```
break_statement
: 'break' ';'
;
```

The target of a `break` statement is the end point of the nearest enclosing `switch`, `while`, `do`, `for`, or `foreach` statement. If a `break` statement is not enclosed by a `switch`, `while`, `do`, `for`, or `foreach` statement, a compile-time error occurs.

When multiple `switch`, `while`, `do`, `for`, or `foreach` statements are nested within each other, a `break` statement applies only to the innermost statement. To transfer control across multiple nesting levels, a `goto` statement ([The goto statement](#)) must be used.

A `break` statement cannot exit a `finally` block ([The try statement](#)). When a `break` statement occurs within a

`finally` block, the target of the `break` statement must be within the same `finally` block; otherwise, a compile-time error occurs.

A `break` statement is executed as follows:

- If the `break` statement exits one or more `try` blocks with associated `finally` blocks, control is initially transferred to the `finally` block of the innermost `try` statement. When and if control reaches the end point of a `finally` block, control is transferred to the `finally` block of the next enclosing `try` statement. This process is repeated until the `finally` blocks of all intervening `try` statements have been executed.
- Control is transferred to the target of the `break` statement.

Because a `break` statement unconditionally transfers control elsewhere, the end point of a `break` statement is never reachable.

The `continue` statement

The `continue` statement starts a new iteration of the nearest enclosing `while`, `do`, `for`, or `foreach` statement.

```
continue_statement
: 'continue' ';'
;
```

The target of a `continue` statement is the end point of the embedded statement of the nearest enclosing `while`, `do`, `for`, or `foreach` statement. If a `continue` statement is not enclosed by a `while`, `do`, `for`, or `foreach` statement, a compile-time error occurs.

When multiple `while`, `do`, `for`, or `foreach` statements are nested within each other, a `continue` statement applies only to the innermost statement. To transfer control across multiple nesting levels, a `goto` statement ([The `goto` statement](#)) must be used.

A `continue` statement cannot exit a `finally` block ([The `try` statement](#)). When a `continue` statement occurs within a `finally` block, the target of the `continue` statement must be within the same `finally` block; otherwise a compile-time error occurs.

A `continue` statement is executed as follows:

- If the `continue` statement exits one or more `try` blocks with associated `finally` blocks, control is initially transferred to the `finally` block of the innermost `try` statement. When and if control reaches the end point of a `finally` block, control is transferred to the `finally` block of the next enclosing `try` statement. This process is repeated until the `finally` blocks of all intervening `try` statements have been executed.
- Control is transferred to the target of the `continue` statement.

Because a `continue` statement unconditionally transfers control elsewhere, the end point of a `continue` statement is never reachable.

The `goto` statement

The `goto` statement transfers control to a statement that is marked by a label.

```
goto_statement
: 'goto' identifier ';'
| 'goto' 'case' constant_expression ';'
| 'goto' 'default' ';'
;
```

The target of a `goto` *identifier* statement is the labeled statement with the given label. If a label with the given

name does not exist in the current function member, or if the `goto` statement is not within the scope of the label, a compile-time error occurs. This rule permits the use of a `goto` statement to transfer control out of a nested scope, but not into a nested scope. In the example

```
using System;

class Test
{
    static void Main(string[] args) {
        string[,] table = {
            {"Red", "Blue", "Green"},
            {"Monday", "Wednesday", "Friday"}
        };

        foreach (string str in args) {
            int row, colm;
            for (row = 0; row <= 1; ++row)
                for (colm = 0; colm <= 2; ++colm)
                    if (str == table[row,colm])
                        goto done;

            Console.WriteLine("{0} not found", str);
            continue;
        done:
            Console.WriteLine("Found {0} at [{1}][{2}]", str, row, colm);
        }
    }
}
```

a `goto` statement is used to transfer control out of a nested scope.

The target of a `goto case` statement is the statement list in the immediately enclosing `switch` statement ([The switch statement](#)), which contains a `case` label with the given constant value. If the `goto case` statement is not enclosed by a `switch` statement, if the *constant expression* is not implicitly convertible ([Implicit conversions](#)) to the governing type of the nearest enclosing `switch` statement, or if the nearest enclosing `switch` statement does not contain a `case` label with the given constant value, a compile-time error occurs.

The target of a `goto default` statement is the statement list in the immediately enclosing `switch` statement ([The switch statement](#)), which contains a `default` label. If the `goto default` statement is not enclosed by a `switch` statement, or if the nearest enclosing `switch` statement does not contain a `default` label, a compile-time error occurs.

A `goto` statement cannot exit a `finally` block ([The try statement](#)). When a `goto` statement occurs within a `finally` block, the target of the `goto` statement must be within the same `finally` block, or otherwise a compile-time error occurs.

A `goto` statement is executed as follows:

- If the `goto` statement exits one or more `try` blocks with associated `finally` blocks, control is initially transferred to the `finally` block of the innermost `try` statement. When and if control reaches the end point of a `finally` block, control is transferred to the `finally` block of the next enclosing `try` statement. This process is repeated until the `finally` blocks of all intervening `try` statements have been executed.
- Control is transferred to the target of the `goto` statement.

Because a `goto` statement unconditionally transfers control elsewhere, the end point of a `goto` statement is never reachable.

The return statement

The `return` statement returns control to the current caller of the function in which the `return` statement

appears.

```
return_statement
: 'return' expression? ';'
;
```

A `return` statement with no expression can be used only in a function member that does not compute a value, that is, a method with the result type ([Method body](#)) `void`, the `set` accessor of a property or indexer, the `add` and `remove` accessors of an event, an instance constructor, a static constructor, or a destructor.

A `return` statement with an expression can only be used in a function member that computes a value, that is, a method with a non-void result type, the `get` accessor of a property or indexer, or a user-defined operator. An implicit conversion ([Implicit conversions](#)) must exist from the type of the expression to the return type of the containing function member.

Return statements can also be used in the body of anonymous function expressions ([Anonymous function expressions](#)), and participate in determining which conversions exist for those functions.

It is a compile-time error for a `return` statement to appear in a `finally` block ([The try statement](#)).

A `return` statement is executed as follows:

- If the `return` statement specifies an expression, the expression is evaluated and the resulting value is converted to the return type of the containing function by an implicit conversion. The result of the conversion becomes the result value produced by the function.
- If the `return` statement is enclosed by one or more `try` or `catch` blocks with associated `finally` blocks, control is initially transferred to the `finally` block of the innermost `try` statement. When and if control reaches the end point of a `finally` block, control is transferred to the `finally` block of the next enclosing `try` statement. This process is repeated until the `finally` blocks of all enclosing `try` statements have been executed.
- If the containing function is not an async function, control is returned to the caller of the containing function along with the result value, if any.
- If the containing function is an async function, control is returned to the current caller, and the result value, if any, is recorded in the return task as described in ([Enumerator interfaces](#)).

Because a `return` statement unconditionally transfers control elsewhere, the end point of a `return` statement is never reachable.

The throw statement

The `throw` statement throws an exception.

```
throw_statement
: 'throw' expression? ';'
;
```

A `throw` statement with an expression throws the value produced by evaluating the expression. The expression must denote a value of the class type `System.Exception`, of a class type that derives from `System.Exception` or of a type parameter type that has `System.Exception` (or a subclass thereof) as its effective base class. If evaluation of the expression produces `null`, a `System.NullReferenceException` is thrown instead.

A `throw` statement with no expression can be used only in a `catch` block, in which case that statement re-throws the exception that is currently being handled by that `catch` block.

Because a `throw` statement unconditionally transfers control elsewhere, the end point of a `throw` statement is never reachable.

When an exception is thrown, control is transferred to the first `catch` clause in an enclosing `try` statement that can handle the exception. The process that takes place from the point of the exception being thrown to the point of transferring control to a suitable exception handler is known as *exception propagation*. Propagation of an exception consists of repeatedly evaluating the following steps until a `catch` clause that matches the exception is found. In this description, the *throw point* is initially the location at which the exception is thrown.

- In the current function member, each `try` statement that encloses the throw point is examined. For each statement `S`, starting with the innermost `try` statement and ending with the outermost `try` statement, the following steps are evaluated:
 - If the `try` block of `S` encloses the throw point and if `S` has one or more `catch` clauses, the `catch` clauses are examined in order of appearance to locate a suitable handler for the exception, according to the rules specified in Section [The try statement](#). If a matching `catch` clause is located, the exception propagation is completed by transferring control to the block of that `catch` clause.
 - Otherwise, if the `try` block or a `catch` block of `S` encloses the throw point and if `S` has a `finally` block, control is transferred to the `finally` block. If the `finally` block throws another exception, processing of the current exception is terminated. Otherwise, when control reaches the end point of the `finally` block, processing of the current exception is continued.
- If an exception handler was not located in the current function invocation, the function invocation is terminated, and one of the following occurs:
 - If the current function is non-async, the steps above are repeated for the caller of the function with a throw point corresponding to the statement from which the function member was invoked.
 - If the current function is async and task-returning, the exception is recorded in the return task, which is put into a faulted or cancelled state as described in [Enumerator interfaces](#).
 - If the current function is async and void-returning, the synchronization context of the current thread is notified as described in [Enumerable interfaces](#).
- If the exception processing terminates all function member invocations in the current thread, indicating that the thread has no handler for the exception, then the thread is itself terminated. The impact of such termination is implementation-defined.

The try statement

The `try` statement provides a mechanism for catching exceptions that occur during execution of a block. Furthermore, the `try` statement provides the ability to specify a block of code that is always executed when control leaves the `try` statement.

```

try_statement
    : 'try' block catch_clause+
    | 'try' block finally_clause
    | 'try' block catch_clause+ finally_clause
    ;

catch_clause
    : 'catch' exception_specifier? exception_filter? block
    ;

exception_specifier
    : '(' type identifier? ')'
    ;

exception_filter
    : 'when' '(' expression ')'
    ;

finally_clause
    : 'finally' block
    ;

```

There are three possible forms of `try` statements:

- A `try` block followed by one or more `catch` blocks.
- A `try` block followed by a `finally` block.
- A `try` block followed by one or more `catch` blocks followed by a `finally` block.

When a `catch` clause specifies an *exception_specifier*, the type must be `System.Exception`, a type that derives from `System.Exception` or a type parameter type that has `System.Exception` (or a subclass thereof) as its effective base class.

When a `catch` clause specifies both an *exception_specifier* with an *identifier*, an **exception variable** of the given name and type is declared. The exception variable corresponds to a local variable with a scope that extends over the `catch` clause. During execution of the *exception_filter* and *block*, the exception variable represents the exception currently being handled. For purposes of definite assignment checking, the exception variable is considered definitely assigned in its entire scope.

Unless a `catch` clause includes an exception variable name, it is impossible to access the exception object in the filter and `catch` block.

A `catch` clause that does not specify an *exception_specifier* is called a general `catch` clause.

Some programming languages may support exceptions that are not representable as an object derived from `System.Exception`, although such exceptions could never be generated by C# code. A general `catch` clause may be used to catch such exceptions. Thus, a general `catch` clause is semantically different from one that specifies the type `System.Exception`, in that the former may also catch exceptions from other languages.

In order to locate a handler for an exception, `catch` clauses are examined in lexical order. If a `catch` clause specifies a type but no exception filter, it is a compile-time error for a later `catch` clause in the same `try` statement to specify a type that is the same as, or is derived from, that type. If a `catch` clause specifies no type and no filter, it must be the last `catch` clause for that `try` statement.

Within a `catch` block, a `throw` statement ([The throw statement](#)) with no expression can be used to re-throw the exception that was caught by the `catch` block. Assignments to an exception variable do not alter the exception that is re-thrown.

In the example

```

using System;

class Test
{
    static void F() {
        try {
            G();
        }
        catch (Exception e) {
            Console.WriteLine("Exception in F: " + e.Message);
            e = new Exception("F");
            throw;           // re-throw
        }
    }

    static void G() {
        throw new Exception("G");
    }

    static void Main() {
        try {
            F();
        }
        catch (Exception e) {
            Console.WriteLine("Exception in Main: " + e.Message);
        }
    }
}

```

the method `F` catches an exception, writes some diagnostic information to the console, alters the exception variable, and re-throws the exception. The exception that is re-thrown is the original exception, so the output produced is:

```

Exception in F: G
Exception in Main: G

```

If the first catch block had thrown `e` instead of rethrowing the current exception, the output produced would be as follows:

```

Exception in F: G
Exception in Main: F

```

It is a compile-time error for a `break`, `continue`, or `goto` statement to transfer control out of a `finally` block. When a `break`, `continue`, or `goto` statement occurs in a `finally` block, the target of the statement must be within the same `finally` block, or otherwise a compile-time error occurs.

It is a compile-time error for a `return` statement to occur in a `finally` block.

A `try` statement is executed as follows:

- Control is transferred to the `try` block.
- When and if control reaches the end point of the `try` block:
 - If the `try` statement has a `finally` block, the `finally` block is executed.
 - Control is transferred to the end point of the `try` statement.
- If an exception is propagated to the `try` statement during execution of the `try` block:
 - The `catch` clauses, if any, are examined in order of appearance to locate a suitable handler for the

exception. If a `catch` clause does not specify a type, or specifies the exception type or a base type of the exception type:

- If the `catch` clause declares an exception variable, the exception object is assigned to the exception variable.
- If the `catch` clause declares an exception filter, the filter is evaluated. If it evaluates to `false`, the catch clause is not a match, and the search continues through any subsequent `catch` clauses for a suitable handler.
- Otherwise, the `catch` clause is considered a match, and control is transferred to the matching `catch` block.
- When and if control reaches the end point of the `catch` block:
 - If the `try` statement has a `finally` block, the `finally` block is executed.
 - Control is transferred to the end point of the `try` statement.
- If an exception is propagated to the `try` statement during execution of the `catch` block:
 - If the `try` statement has a `finally` block, the `finally` block is executed.
 - The exception is propagated to the next enclosing `try` statement.
- If the `try` statement has no `catch` clauses or if no `catch` clause matches the exception:
 - If the `try` statement has a `finally` block, the `finally` block is executed.
 - The exception is propagated to the next enclosing `try` statement.

The statements of a `finally` block are always executed when control leaves a `try` statement. This is true whether the control transfer occurs as a result of normal execution, as a result of executing a `break`, `continue`, `goto`, or `return` statement, or as a result of propagating an exception out of the `try` statement.

If an exception is thrown during execution of a `finally` block, and is not caught within the same finally block, the exception is propagated to the next enclosing `try` statement. If another exception was in the process of being propagated, that exception is lost. The process of propagating an exception is discussed further in the description of the `throw` statement ([The throw statement](#)).

The `try` block of a `try` statement is reachable if the `try` statement is reachable.

A `catch` block of a `try` statement is reachable if the `try` statement is reachable.

The `finally` block of a `try` statement is reachable if the `try` statement is reachable.

The end point of a `try` statement is reachable if both of the following are true:

- The end point of the `try` block is reachable or the end point of at least one `catch` block is reachable.
- If a `finally` block is present, the end point of the `finally` block is reachable.

The checked and unchecked statements

The `checked` and `unchecked` statements are used to control the *overflow checking context* for integral-type arithmetic operations and conversions.

```
checked_statement
: 'checked' block
;

unchecked_statement
: 'unchecked' block
;
```

The `checked` statement causes all expressions in the *block* to be evaluated in a checked context, and the

`unchecked` statement causes all expressions in the *block* to be evaluated in an unchecked context.

The `checked` and `unchecked` statements are precisely equivalent to the `checked` and `unchecked` operators ([The checked and unchecked operators](#)), except that they operate on blocks instead of expressions.

The lock statement

The `lock` statement obtains the mutual-exclusion lock for a given object, executes a statement, and then releases the lock.

```
lock_statement
: 'lock' '(' expression ')' embedded_statement
;
```

The expression of a `lock` statement must denote a value of a type known to be a *reference_type*. No implicit boxing conversion ([Boxing conversions](#)) is ever performed for the expression of a `lock` statement, and thus it is a compile-time error for the expression to denote a value of a *value_type*.

A `lock` statement of the form

```
lock (x) ...
```

where `x` is an expression of a *reference_type*, is precisely equivalent to

```
bool __lockWasTaken = false;
try {
    System.Threading.Monitor.Enter(x, ref __lockWasTaken);
    ...
}
finally {
    if (__lockWasTaken) System.Threading.Monitor.Exit(x);
}
```

except that `x` is only evaluated once.

While a mutual-exclusion lock is held, code executing in the same execution thread can also obtain and release the lock. However, code executing in other threads is blocked from obtaining the lock until the lock is released.

Locking `System.Type` objects in order to synchronize access to static data is not recommended. Other code might lock on the same type, which can result in deadlock. A better approach is to synchronize access to static data by locking a private static object. For example:

```

class Cache
{
    private static readonly object synchronizationObject = new object();

    public static void Add(object x) {
        lock (Cache.synchronizationObject) {
            ...
        }
    }

    public static void Remove(object x) {
        lock (Cache.synchronizationObject) {
            ...
        }
    }
}

```

The using statement

The `using` statement obtains one or more resources, executes a statement, and then disposes of the resource.

```

using_statement
: 'using' '(' resource_acquisition ')' embedded_statement
;

resource_acquisition
: local_variable_declaration
| expression
;

```

A **resource** is a class or struct that implements `System.IDisposable`, which includes a single parameterless method named `Dispose`. Code that is using a resource can call `Dispose` to indicate that the resource is no longer needed. If `Dispose` is not called, then automatic disposal eventually occurs as a consequence of garbage collection.
